### **Preface**

The AT&T C++ Language System Product Reference Manual provides a complete definition of the C++ language supported by Release 2.0 of the C++ Language System. The manual is part of a set of four documents that are supplied with your C++ Language System. The other documents are:

- the Release Notes, which describe the contents of this release, how to install it, and changes to the language
- the Selected Readings, which contains papers describing aspects of the C++ language
- the Library Manual, which describes the three C++ class libraries and tells you how to use them

This manual contains 16 sections covering the various aspects of the C++ language:

- 1. Introduction
- 2. Lexical Conventions
- 3. Basic Concepts
- 4. Standard Conversions
- 5. Expressions
- 6. Statements
- 7. Declarations
- 8. Declarators
- 9. Classes
- 10. Derived Classes
- 11. Member Access Control
- 12. Special Member Functions
- 13. Overloading
- 14. Templates (experimental)
- 15. Exception Handing (experimental)
- 16. Compiler Control Lines

Sections 14 and 15 are place markers for experimental features that are not implemented in Release 2.0.

The Reference Manual proper is followed by appendices that describe grammar, compatibility, and product-specific behavior in Release 2.0:

- Appendix A: Grammar Summary
- Appendix B: Compatibility
- Appendix C: Implementation-Specific Behavior describes behavior of the Release 2.0 Language System that is implementation specific

-
ж

■ Appendix D: Not Implemented Messages — lists error messages that result when you attempt to use a feature not implemented in Release 2.0, and describes the unimplemented feature

To make the best use of the *Product Reference Manual*, you should be familiar with the C programming language and the C programming environment under the UNIX® operating system. Refer to Appendix B of the *Release Notes* for further sources of information about these topics.

### C++ Reference Manual

This reference manual is by Bjarne Stroustrup.

This is the May 1989 draft of the C++ Reference Manual

### Introduction

This manual describes the C++ programming language as of May 1989. C++ is a general purpose programming language based on the C programming language\*. In addition to the facilities provided by C, C++ provides classes, templates, exception handling, inline functions, operator overloading, function name overloading, constant types, references, free store management operators, and function argument checking and type conversion. These extensions to C are summarized in §B.1. The differences between C++ and ANSI C+ are summarized in §B.2. The extensions to C++ since the 1985 edition of this manual are summarized in §B.1.2. The sections related to templates (§14) and exception handling (§15) are placeholders for planned language extensions.

### 1.1 Overview

This manual is organized like this:

- 1. Introduction
- 2. Lexical Conventions (p. 3)
- 3. Basic Concepts (p. 7)
- 4. Standard Conversions (p. 12)
- 5. Expressions (p. 15)
- 6. Statements (p. 28)
- 7. Declarations (p. 34)
- 8. Declarators (p. 42)
- 9. Classes (p. 54)

- 10. Derived Classes (p. 63)
- 11. Member Access Control (p. 70)
- 12. Special Member Functions (p. 75)
- 13. Overloading (p. 86)
- 14. Templates (experimental) (p. 96)
- 15. Exception Handling (experimental) (p. 97)
- 16. Compiler Control Lines (p. 98)
  - Appendix A: Grammar Summary (p. 100)
  - Appendix B: Compatibility (p. 109)

<sup>&</sup>quot;The C Programming Language" by Brian W. Kernighan and Dennis M. Ritchie, Prentice Hall, 1978

Draft Proposed American National Standard X3J11/88-090 dated Dec 7, 1988. Copyright © 1989 by AT&T.

# 1.2 Syntax Notation

In the syntax notation used in this manual, syntactic categories are indicated by *italic* type, and literal words and characters in constant width type. Alternatives are listed on separate lines except in a few cases where a long set of alternatives is presented on one line, marked by the phrase "one of." An optional terminal or non-terminal symbol is indicated by the subscript "opt," so that

{ expressionopt }

indicates an optional expression enclosed in braces.

### 2. Lexical Conventions

A C++ program consists of one or more translation units §3.3. A translation unit is conceptually translated in several phases. The first of these is preprocessing (§16), which performs file inclusion and macro substitution. Preprocessing is controlled by directives introduced by lines where the first non-whitespace character (§2.1) is \*. When preprocessing is complete, a translation unit consists of a sequence of tokens. The word file is used to refer to a translation unit after preprocessing.

#### 2.1 Tokens

There are six kinds of tokens: identifiers, keywords, constants, strings, operators, and other separators. Blanks, horizontal and vertical tabs, new-lines, formfeeds, and comments (collectively, "white space"), as described below, are ignored except as they serve to separate tokens. Some white space is required to separate otherwise adjacent identifiers, keywords, and constants.

If the input stream has been parsed into tokens up to a given character, the next token is taken to be the longest string of characters that could possibly constitute a token.

#### 2.2 Comments

The characters /\* start a comment, which terminates with the characters \*/. These comments do not nest. The characters // start a comment, which terminates at the end of the line on which they occur. The comment characters //, /\*, and \*/ have no special meaning within a // comment and are treated just like other characters. Similarly, the comment characters // and /\* have no special meaning within a /\* comment.

#### 2.3 Identifiers

An identifier is an arbitrarily long sequence of letters and digits. The first character must be a letter; the underscore \_ counts as a letter. Upper- and lower-case letters are different. All characters are significant.

# 2.4 Keywords

The following identifiers are reserved for use as keywords, and may not be used otherwise:

asm	continue	float	new	signed	union
auto	default	for	operator	sizeof	unsigned
break	delete	friend	private	static	virtual
case	do	goto	protected	struct	void
catch	double	if	public	switch	volatile
char	else	inline	register	template	while
class	enum	int	return	this	
const	extern	long	short	typedef	

In addition, identifiers containing a double underscore are reserved for use by C++ implementations and standard libraries and should be avoided by users.

The ASCII representation of C++ programs uses the following characters as operators or for punctuation:

!	ક	^	&	*	(	)	-	+	=
{	}		~	[	]	1	;	,	:
**	<	>	?			/			

and the following character combinations are used as operators:

Each is a single token.

In addition, the following tokens are used by the preprocessor:

Certain implementation dependent properties, such as the type of a sizeof (§5.3.2) and the ranges of fundamental types (§3.6.1), are defined in standard header files (§16.2):

```
<stddef.h> <limits.h> <stdlib.h>
```

These headers are part of the ANSI C standard.

#### 2.5 Literals

There are several kinds of literal constants:

literal:

integer-constant character-constant floating-constant string

### 2.5.1 Integer Constants

An integer constant consisting of a sequence of digits is taken to be decimal (base ten) unless it begins with 0 (digit zero). A sequence of digits starting with 0 is taken to be an octal integer (base eight). The digits 8 and 9 are not octal digits. A sequence of digits preceded by 0x or 0x is taken to be a hexadecimal integer (base sixteen). The hexadecimal digits include a or A through f or F with decimal values 10 through 15. For example, the number twelve can be written 12, 014, or 0xC.

The type of an integer constant depends on its form, value, and suffix. If it is decimal and has no suffix, it has the first of these types in which its value can be represented: int, long int, unsigned long int. If it is octal or hexadecimal and has no suffix, it has the first of these types in which its value can be represented: int, unsigned int, long int, unsigned long int. If it is suffixed by u or U, its type is the first of these types in which its value can be represented: unsigned int, unsigned long int. If it is suffixed by 1 or L, its type is the first of these types in which its value can be represented: long int, unsigned long int. If it is suffixed by ul, lu, uL, Lu, Ul, UL, or LU, its type is unsigned long int.

For example, 100000 is of type int on a machine with 32 bit ints, but of type long int on a machine with 16 bit ints and 32 bit longs. Similarly, 0XA000 is of type int on a machine with 32 bit ints, but of type unsigned int on a machine with 16 bit ints. These implementation dependencies can in many cases be avoided by using suffixes: 100000L is long int on all machines and 0XA000U is of type unsigned int on all machines with at least 16 bits used to represent an unsigned int.

#### 2.5.2 Character Constants

A character constant is one or more characters enclosed in single quotes, as in 'x'. Single character constants have type char. The value of a single character constant is the numerical value of the character in the machine's character set. Multicharacter constants have type int. The value of a multicharacter constant is implementation dependent.

Certain non-graphic characters, the single quote ', the double quote ", the question mark ?, and the backslash \, may be represented according to the following table of escape sequences:

new-line	NL (LF)	\n
horizontal tab	HT	\t
vertical tab	VT	\v
backspace	BS	\b
carriage return	CR	\r
form feed	FF	\f
alert	BEL	\a
backslash	1	11
question mark	?	/?
single quote	•	\'
double quote	**	/ "
octal number	000	\000
hex number	hhh	\xhhh

If the character following a backslash is not one of those specified, the behavior is undefined. An escape sequence specifies a single character.

The escape \ooo consists of the backslash followed by one, two, or three octal digits that are taken to specify the value of the desired character. The escape \xhhh consists of the backslash followed by x followed by a sequence of hexadecimal digits that are taken to specify the value of the desired character. There is no limit to the number of hexadecimal digits in the sequence. A sequence of octal or hexadecimal digits is terminated by the first character that is not an octal digit or a hexadecimal digit, respectively. The value of a character constant is implementation dependent if it exceeds that of the largest char.

A character constant immediately preceded by the letter L, for example L'ab', is a widecharacter constant. A wide-character constant is of type wchar\_t, an integral type (§3.6.1) defined in the standard header <stddef.h>. Wide characters are intended for character sets where a character does not fit into a single byte.

### 2.5.3 Floating Constants

A floating constant consists of an integer part, a decimal point, a fraction part, an e or E, an optionally signed integer exponent, and an optional type suffix. The integer and fraction parts both consist of a sequence of decimal (base ten) digits. Either the integer part or the fraction part (not both) may be missing; either the decimal point or the letter e (or E) and the exponent (not both) may be missing. The type of a floating constant is double unless explicitly specified by a suffix. The suffixes f and F specify float, the suffixes 1 and L specify long double.

# 2.5.4 String Literals

A string literal is a sequence of characters (as defined in §2.5.2) surrounded by double quotes, as in "...". A string has type "array of char" and storage class static (§3.5), and is initialized with the given characters. Whether all string literals are distinct (that is, are stored in non-overlapping objects) is implementation dependent. The effect of attempting to modify a string literal is undefined.

Adjacent string literals are concatenated. Characters in concatenated strings are kept distinct. For example

contains the two characters '\xA' and 'B' after concatenation (and not the single hexadecimal character '\xAB').

After any necessary concatenation '\0' is appended so that programs that scan a string can find its end. The size of a string is the number of its characters including this terminator. Within a string, the double quote character " must be preceded by a \.

A string literal immediately preceded by the letter L, for example L"asdf", is a widecharacter string. A wide-character string is of type "array of wchar\_t," where wchar\_t is an integral type defined in the standard header <stddef.h>. Concatenation of ordinary and wide-character string literals is undefined.

# 3. Basic Concepts

A name denotes an object, a function, a set of functions, a type, a class member, a template, a value, or a label. A name is introduced into a program by a declaration. A name can be used only within a region of program text called its scope. A name has a type, which determines its use. A name used in more than one translation unit may (or may not) refer to the same object. function, type, template, or value in these translation units depending on the linkage (§3.3) specified in the translation units.

An object is a region of storage (§3.7). A named object has a storage class (§3.5) that determines its lifetime. The meaning of the values found in an object is determined by the type of the expression used to access it.

### 3.1 Declarations and Definitions

A declaration (§7) introduces one or more names into a program. A declaration is a definition unless it declares a function without specifying the body (§8.3), it contains the extern specifier (§7.1.1) and no initializer or function body, it is the declaration of a static data member in a class declaration (§9.4), or it is a class name declaration (§9.1). For example, these are definitions:

```
int a;
extern const c = 1;
int f(int x) { return x+a; }
struct S { int a; int b; };
enum { up, down };
```

whereas these are just declarations:

```
extern int a;
extern const c;
int f(int);
struct S;
typedef int Int;
```

# 3.2 Scopes

There are four kinds of scope: local, function, file, and class.

Local: A name declared in a block (§6.3) is local to that block and can be used only in it and in blocks enclosed by it after the point of declaration. Names of formal arguments for a function are treated as if they were declared in the outermost block of that function.

Function: Labels (§6.1) can be used anywhere in the function in which they are declared. Only labels have function scope.

File: A name declared outside all blocks (§6.3) and classes (§9) has file scope and can be used in the file in which it is declared after the point of declaration. Names declared with file scope are said to be global.

Class: The name of a class member is local to its class and can be used only in a member function of that class (§9.3), after the . operator applied to an object of its class (§5.2.4), after the -> operator applied to a pointer to an object of its class (§5.2.4), or after the :: scope resolution operator (§5.1) applied to the name of its class or a class derived from (§10) its class. A class, enumeration (§7.2), or a typedef-name declared within a class (§9.7) is not considered a member and its name belongs to the enclosing scope; the same is true for a name declared by a friend declaration (§11.4).

A name may be hidden by an explicit declaration of that same name in an enclosed block or in a class. A hidden class member name can still be used when it is qualified by its class name using the :: operator (§5.1, §9.4, §10). A hidden name of an object, function, or enumerator with file scope can still be used when it is qualified by the unary :: operator (§5.1). In addition, a class name (§9.1) may be hidden by the name of an object, function, or enumerator declared in the same scope. If a class and an object, function, or enumerator are declared in the same scope (in any order) with the same name the class name is hidden. A class name hidden by a name of an object, function, or enumerator can still be used when appropriately (§7.1.6) prefixed with class, struct, or union. The scope rules are summarized in §10.4.

The point of declaration for a name is immediately after its complete declarator (§8) and before its initializer (if any). For example,

```
int x:
\{ int x = x; \}
```

Here the second x is initialized with its own (unspecified) value.

### 3.3 Program and Linkage

A program consists of one or more files (§2) linked together. A file consists of a sequence of declarations.

A name of file scope that is explicitly declared static is local to its file and can be used as a name for other objects, functions, etc., in other files. Such names are said to have internal linkage. A name of file scope that is explicitly declared const or inline and not explicitly declared extern is local to its file. So is the name of a class that has not been used in the declaration of an object or function that is not local to its file and has no static members (§9.4) and no non-inline member functions (§9.3.2). Every declaration of a particular name of file scope that is not declared to have internal linkage in one of these ways in a multi-file program refers to the same object (§3.7), function (§8.2.5), or class (§9). Such names are said to be external or to have external linkage. In particular, since it is not possible to declare a class name static, every use of a particular file scope class name in a program that has been used in the declaration of an object or function with external linkage or has a static member or a non-inline member function refers to the same class.

Typedef names (§7.1.3), enumerators (§7.2), and template names (§14) do not have external linkage.

Static class members (§9.4) have external linkage.

Local names (§3.2) explicitly declared extern have external linkage.

The types specified in all declarations of a particular external name must be identical except for the use of typedef names (§7.1.3) and unspecified array bounds (§8.2.4). There must be exactly one definition for each function, object, and class in a program.

A function may be defined only in file or class scope.

Linkage to non-C++ declarations can be achieved using a linkage-specification (§7.4).

#### 3.4 Start and Termination

A program must contain a function called main(). This function is the designated start of the program. This function is not predefined by the compiler, it cannot be overloaded, and its type is implementation dependent. It is recommended that the two examples below be allowed on any implementation and that any further arguments required be added after argv. The function main() may be defined as:

int main() { /\* ... \*/ }

or

int main(int argc, char\* argv[]) { /\* ... \*/ }

In the latter case argc shall be the number of parameters passed to the program from an environment in which the program is run. If argc is non-zero these parameters shall be supplied as zero-terminated strings in argv[0] through argv[argc-1] and argv[0] shall be the name used to invoke the program or "". It is guaranteed that argv[argc] == 0.

main() may not be called from within a program.

The value returned by main() is returned to the program's environment as the value of the program.

Calling the function

void exit(int)

declared in <stdlib.h> terminates the program. The argument value is returned to the program's environment as the value of the program.

The initialization of static objects (§3.5) from a file is done before the first use of any function or object defined in that file. Such initializations (§8.4, §9.4, §12.1, §12.6.1) may be done before the first statement of main () or deferred to any point in time before the first use of a function or object defined in that file. The default initialization of all static objects to zero (§8.4) is performed before any dynamic (i.e., run-time) initialization. No further order is imposed on the initialization of objects from different files.

Destructors (§12.4) for initialized static objects are called when returning from main () and when calling exit(). Destruction is done in reverse order of initialization. The function atexit() from <stdlib.h> can be used to specify that a function must be called at exit. In this case, objects initialized before an atexit () call may not be destroyed until after the function specified in the atexit() call have been called. Where a C++ implementation coexists with a C implementation, any actions specified by the C implementation to take place after the atexit() functions have been called take place after all destructors have been called.

Calling the function

void abort ()

declared in <stdlib.h> terminates the program without executing destructors for static

### 3.5 Storage Classes

There are two declarable storage classes: automatic and static.

Automatic objects are local to each invocation of a block.

Static objects exist and retain their values throughout the execution of the entire program.

Local objects are initialized (§12.1) each time their block is entered and destroyed (§12.4) upon exit from it. Static objects are initialized and destroyed as described in §3.4 and §6.7. Some objects are not associated with names; see §5.3.3 and §12.2. All global objects have storage class static. Local objects and class members can be given static storage class by explicit use of the static storage class specifier (§7.1.1).

### 3.6 Types

There are two kinds of types: fundamental types and derived types.

### 3.6.1 Fundamental Types

There are several fundamental types. The standard header limits.h> specifies the largest and smallest values of each for an implementation.

Objects declared as characters (char) are large enough to store any member of the implementation's basic character set. If a character from this set is stored in a character variable, its value is equivalent to the integer code of that character. Characters may be explicitly declared unsigned or signed. A plain char is either a signed char, or an unsigned char, but it is implementation dependent which. A signed char and an unsigned char consume the same amount of space.

Up to three sizes of integer, declared short int, int, and long int, are available. Longer integers provide no less storage than shorter ones, but the implementation may make either short integers, or long integers, or both, equivalent to plain integers. "Plain" integers have the natural size suggested by the machine architecture; the other sizes are provided to meet special needs.

Unsigned integers, declared unsigned, obey the laws of arithmetic modulo  $2^n$  where n is the number of bits in the representation. This implies that unsigned arithmetic does not overflow.

There are three *floating* types: float, double, and long double. The type double provides no less precision than float, and the type long double provides no less precision than double.

Types char, int of all sizes, and enumerations (§7.2) are collectively called *integral* types. *Integral* and *floating* types are collectively called *arithmetic* types.

The void type specifies an empty set of values. The (nonexistent) value of a void object may not be used in any way, and neither explicit nor implicit conversions to a non-void type may be applied. Because a void expression denotes a nonexistent value, such an expression may be used only as an expression statement (§6.2), as the left operand of a comma expression (§5.18), or as a second or third operand of ?: (§5.16). No object of type void may be declared. Any expression may be explicitly converted to type void (§5.4).

### 3.6.2 Derived Types

There is a conceptually infinite number of derived types constructed from the fundamental types in the following ways:

arrays of objects of a given type, §8.2.4;

functions, which take arguments of given types and return objects of a given type, §8.2.5; pointers to objects or functions of a given type, §8.2.1;

references to objects or functions of a given type, §8.2.2;

constants, which are values of a given type, §7.1.6;

classes containing a sequence of objects of various types (§9), a set of functions for manipulating these objects (§9.3), and a set of restrictions on the access to these objects and functions, §11;

structures, which are classes without default access restrictions, §11;

unions, which are structures capable of containing objects of different types at different times, §9.5;

pointers to class members, which identify members of a given type within objects of a given class, §8.2.3.

In general, these methods of constructing objects can be applied recursively; restrictions are mentioned in §8.2.5, §8.2.4, §8.2.1, and §8.2.2.

A pointer to objects of a type T is referred to as a "pointer to T." For example, a pointer to an object of type int is referred to as "pointer to int" and a pointer to an object of class X is called a "pointer to x."

Objects of type void\* (pointer to void), const void\*, and volatile void\* can be used to point to objects of unknown type. A void\* must have sufficient bits to hold any object pointer.

### 3.6.3 Type Names

Fundamental and derived types can be given names by the typedef mechanism (§7.1.3), and families of types and functions can be specified and named by the template mechanism (§14).

#### 3.7 Lvalues

An object is a region of storage; an lvalue is an expression referring to an object. An obvious example of an Ivalue expression is the name of an object. Some operators yield Ivalues. For example, if E is an expression of pointer type, then \*E is an Ivalue expression referring to the object to which E points. The name "Ivalue" comes from the assignment expression E1 = E2 in which the left operand E1 must be an Ivalue expression. The discussion of each operator below indicates whether it expects Ivalue operands and whether it yields an Ivalue. An Ivalue is modifiable if it is not a function name, an array name, or const.

### 4. Standard Conversions

A number of operators may, depending on their operands, cause conversion of the value of an operand from one type to another. This section summarizes the conversions demanded by most ordinary operators and explains the result to be expected from such conversions; it will be supplemented as required by the discussion of each operator. §12.3 and §13.2 describe user-defined conversions and their interaction with standard conversions. The result of a conversion is an Ivalue only if the result is a reference (§8.2.2).

# 4.1 Integral Promotions

A char, a short int, enumerator, object of enumeration type (§7.2), or an int bit-field (§9.6) (in both their signed and unsigned varieties) may be used wherever an integer may be used. If an int can represent all the values of the original type, the value is converted to int; otherwise it is converted to unsigned int. This process is called *integral promotion*.

# 4.2 Integral Conversions

When an integer is converted to an *unsigned* type, the value is the least unsigned integer congruent to the signed integer (modulo  $2^n$  where n is the number of bits used to represent the unsigned type). In a 2's complement representation, this conversion is conceptual and there is no actual change in the bit pattern.

When an integer is converted to a signed type, the value is unchanged if it can be represented in the new type; otherwise the value is implementation dependent.

### 4.3 Float and Double

Single-precision floating point arithmetic may be used for float expressions. When a less precise floating value is converted to an equally or more precise floating type, the value is unchanged. When a more precise floating value is converted to a less precise floating type and the value is within representable range, the result may be either the next higher or the next lower representable value. If the result is out of range, the behavior is undefined.

# 4.4 Floating and Integral

Conversion of a floating value to an integral type truncates; that is, the fractional part is discarded. Such conversions are machine dependent; for example, the direction of truncation of negative numbers varies from machine to machine. The result is undefined if the value will not fit in the space provided.

Conversions of integral values to floating type are as mathematically correct as the hardware allows. Loss of precision occurs if an integral value cannot be represented exactly as a value of the floating type.

### 4.5 Arithmetic Conversions

A great many operators cause conversions and yield result types in a similar way. This pattern will be called the "usual arithmetic conversions."

If either operand is of type long double, the other is converted to long double.

Otherwise, if either operand is double, the other is converted to double.

Otherwise, if either operand is float, the other is converted to float.

Otherwise, the integral promotions (§4.1) are performed on both operands.

Then, if either operand is unsigned long the other is converted to unsigned long.

Otherwise, if one operand is a long int and the other unsigned int, then if a long int can represent all the values of an unsigned int, the unsigned int is converted to a long int; otherwise both operands are converted to unsigned long int.

Otherwise, if either operand is long, the other is converted to long.

Otherwise, if either operand is unsigned, the other is converted to unsigned.

Otherwise, both operands are int.

### 4.6 Pointer Conversions

The following conversions may be performed wherever pointers (§8.2.1) are assigned, initialized, compared, etc.:

A constant expression (§5.19) that evaluates to 0 is converted to a pointer, commonly called the null pointer. It is guaranteed that this value will produce a pointer distinguishable from a pointer to any object.

A pointer to any object type may be converted to a void\*.

A pointer to function may be converted to a void\* provided a void\* has sufficient bits to hold it.

A pointer to a class may be converted to a pointer to a public base class of that class (§10) provided this conversion can be done unambiguously (§10.1.1). The result of the conversion is a pointer to the base class sub-object of the derived class object. The null pointer (0) is converted into itself.

An expression with type "array of T" may be converted to a pointer to the initial element of the array.

An expression with type "function returning T" is converted to "pointer to function returning T" except when used as the operand of the address-of operator & or the function call operator ().

### 4.7 Reference Conversions

The following conversion may be performed wherever references (§8.2.2) are initialized (including argument passing (§5.2.2) and function value return (§6.6.3)):

A reference to a class may be converted to a reference to a public base class of that class (§8.4.3) provided this conversion can be done unambiguously (§10.1.1). The result of the conversion is a reference to the base class sub-object of the derived class object.

### 4.8 Pointers to Members

The following conversion may be performed wherever pointers to members (§8.2.3) are initialized, assigned, compared, etc.:

A constant expression (§5.19) that evaluates to 0 is converted to a pointer to member. It is guaranteed that this value will produce a pointer to member distinguishable from any pointer to member.

A pointer to a member of a class may be converted to a pointer to member of a class derived from that class provided the derivation was public and provided this conversion can be done unambiguously (§10.1.1).

The rule for conversion of pointers to members (from pointer to member of base to pointer to member of derived) appears inverted compared to the rule for pointers to objects (from pointer to derived to pointer to base) (§4.6, §10). This inversion is necessary to ensure type safety.

Note that a pointer to member is not a pointer to object or a pointer to function and the rules for conversions of such pointers do not apply to pointers to members. In particular, a pointer to member cannot be converted to a void\*.

# **Expressions**

An expression is a sequence of operators and operands that specifies a computation. An expression may result in a value and it may cause side effects.

This section defines the syntax, order of evaluation, and meaning of expressions.

Operators can be overloaded, that is, given meaning when applied to expressions of class type (§9). Uses of overloaded operators are transformed into function calls as described in §13.4. Overloaded operators obey the rules for syntax specified in this section, but the requirements of operand type, Ivalue, and evaluation order are replaced by the rules for function call. Relations between operators, such as ++a meaning a+=1, are not guaranteed for overloaded operators (§13.4). Operator overloading cannot modify the rules for operators applied to types for which they are defined in this section.

The order of evaluation of subexpressions is determined by the precedence and grouping of the operators. The usual mathematical rules for associativity and commutativity of operators may be applied only where the operators really are associative and commutative. Except where noted, the order of evaluation of operands of individual operators is undefined. In particular, if a value is modified twice in an expression, the result of the expression is undefined except where an ordering is guaranteed by the operators involved. For example:

```
i = v[i++];
                 // the value of 'i' is undefined
                 // 'i' becomes 9
i=7, i++, i++;
```

The handling of overflow and divide check in expression evaluation is implementation dependent. Most existing implementations of C++ ignore integer overflows. Treatment of division by 0 and all floating-point exceptions varies among machines, and is usually adjustable by a library function.

Except where noted, operands of types const T, volatile T, T&, const T&, and volatile TE can be used as if they were of the "plain" type T. Similarly, except where noted, operands of type T\*const and T\*volatile can be used as if they were of the "plain" type T\*. Such usages do not count as standard conversions when considering overloading resolution (§13.2).

If an expression has the type "reference to T" (§8.2.2, §8.4.3), the value of the expression is the object of type "T" denoted by the reference. The expression is an Ivalue. A reference can be thought of as a name of an object.

User-defined conversions of class objects to and from fundamental types, pointers, etc., can be defined (§12.3). If unambiguous (§13.2), such conversions may be applied wherever a class object appears as an operand of an operator, as an initializer (§8.4), as the controlling expression in a selection (§6.4) or iteration (§6.5) statement, as a function return value (§6.6.3), or as a function argument (§5.2.2).

# **5.1 Primary Expressions**

Primary expressions are literals, names, and names qualified by the scope resolution operator ::.

```
primary-expression:
        literal
       this
        :: identifier
        :: operator-function-name
        (expression)
```

A literal is a primary expression. Its type depends on its form (§2.5).

The keyword this is a local variable in the body of a non-static member function (§9.3); it is a pointer to the object for which the function was invoked. The keyword this cannot be used outside of a class member function body.

The operator:: followed by an *identifier* or an *operator-function-name* is a primary expression. Its type is specified by the declaration of the identifier or *operator-function-name*. The result is the identifier or *operator-function-name*. The result is an Ivalue if the identifier is. The identifier or *operator-function-name* must be of file scope. The identifier may not be a class or type name. The identifier may be hidden by a type name. Use of:: allows an object or a function to be referred to even if its identifier has been hidden (§3.2).

A parenthesized expression is a primary expression whose type and value are identical to those of the unadorned expression. The presence of parentheses does not affect whether the expression is an Ivalue.

A name is a restricted form of a primary-expression that can appear after . and -> (§5.2.4):

```
name
```

```
identifier
operator-function-name
conversion-function-name
qualified-name
```

An identifier is a name provided it has been suitably declared (§7). For operator-function-names see §13.4. For conversion-function-names see §12.3.2.

#### qualified-name:

```
class-name :: identifier
class-name :: operator-function-name
```

class-name :: conversion-function-name

class-name :: class-name class-name :: ~ class-name

A class-name (§9.1) followed by :: and the name of a member of that class (§9.2), or a member of a base of that class (§10), is a qualified-name; its type is the type of the member. The result is the member. The result is an Ivalue if the member is. The class-name may be hidden by a non-type name; in this case the class-name is still found and used. Where class-name: class-name or class-name: class-name is used the two class-names must refer to the same class; this notation names constructors (§12.1) and destructors (§12.4), respectively.

### 5.2 Postfix Expressions

Postfix expressions group left-to-right.

```
postfix-expression:
    primary-expression
    postfix-expression [ expression ]
    postfix-expression ( expression-listopt )
    simple-type-name ( expression-listopt )
    postfix-expression . name
    postfix-expression -> name
    postfix-expression ++
    postfix-expression --

expression-list:
    assignment-expression
```

expression-list, assignment-expression

#### 5.2.1 Subscripting

A postfix expression followed by an expression in square brackets is a postfix expression. The intuitive meaning is that of a subscript. One of the expressions must have the type "pointer to T" and the other must be of integral type. The type of the result is "T." The expression E1 [E2] is identical (by definition) to \*((E1)+(E2)). See §5.3 and §5.7 for details of \* and + and §8.2.4 for details of arrays.

#### 5.2.2 Function Call

A function call is a postfix expression followed by parentheses containing a possibly empty, comma-separated list of expressions which constitute the actual arguments to the function. The postfix expression must be of type "function returning T," "pointer to function returning T," or "reference to function returning T," and the result of the function call is of type "T."

When a function is evaluated, each formal argument is initialized (§8.4.3, §12.8, §12.1) with its actual argument. Standard (§4) and user-defined (§12.3) conversions are performed. A function may change the values of its non-constant formal arguments, but these changes cannot affect the values of the actual arguments except where a formal argument is of a nonconst reference type (§8.2.2). Where a formal argument is of reference type a temporary variable is introduced if the actual argument is a constant (§7.1.6, §2.5, §2.5.4, §8.2.4) or of a type that requires type conversion (§12.2). In addition, it is possible to modify the values of non-constant objects through pointer arguments.

A function may be declared to accept fewer arguments (by declaring default arguments §8.2.6) or more arguments (by using the ellipsis, ... §8.2.5) than are specified in the function definition (§8.3).

A function can only be called if a declaration of it is accessible from the scope of the call. This implies that, except where the ellipsis (...) is used, a formal argument is available for each actual argument.

Any actual argument of type float for which there is no formal argument is converted to double before the call; any of type char, short, etc., for which there is no formal argument is converted to int or unsigned by integral promotion (§4.1). An object of a class for which a constructor is declared cannot be passed as an argument except where a formal argument of an appropriate type is declared. In that case the formal argument is initialized with the actual argument by a constructor call before the function is entered (§12.2, §12.8).

The order of evaluation of arguments is implementation dependent; take note that compilers differ. All side effects of argument expressions take effect before the function is entered. The order of evaluation of the postfix expression and the argument expression list is implementation dependent.

Recursive calls are permitted.

A function call is an Ivalue only if the result type is a reference.

### 5.2.3 Explicit Type Conversion

A simple-type-name (§7.1.6) followed by a possibly empty parenthesized expression (or an expression-list if the type is a class with a suitably declared constructor (§8.4)) causes the value of the expression to be converted to the named type; see also (§5.4). The parentheses may only be empty if the type is a class with a suitably declared constructor.

### 5.2.4 Class Member Access

A postfix expression followed by a dot (.) followed by a name is a postfix expression. The first expression must be a class object, and the name must name a member of that class. The result is the named member of the object, and it is an Ivalue if the member is an Ivalue.

A postfix expression followed by an arrow (->) followed by a *name* is a postfix expression. The first expression must be a pointer to a class object and the *name* must name a member of that class. The result is the named member of the object to which the pointer points, and it is an Ivalue if the member is an Ivalue. Thus the expression E1->MOS is the same as (\*E1).MOS.

Note that "class objects" can be structures (§9.2) and unions (§9.5). Classes are discussed in §9.

#### 5.2.5 Increment and Decrement

The value obtained by applying a postfix ++ is the value of the operand. The operand must be a modifiable lvalue. After the result is noted, the object is incremented by 1. The type of the result is the same as the type of the operand, but it is not an lvalue. See the discussions of addition (§5.7) and assignment operators (§5.17) for information on conversions.

The operand of postfix -- is decremented analogously to the postfix ++ operator.

### **5.3 Unary Operators**

Expressions with unary operators group right-to-left.

```
unary-expression:
    postfix-expression
    ++ unary-expression
    -- unary-expression
    unary-operator cast-expression
    sizeof unary-expression
    sizeof ( type-name )
    allocation-expression
    deallocation-expression
unary-operator: one of
```

\* & + -

The unary \* operator means *indirection*: the expression must be a pointer, and the result is an lvalue referring to the object to which the expression points. If the type of the expression is "pointer to T," the type of the result is "T."

The result of the unary & operator is a pointer to its operand. The operand must be a function, an Ivalue, or a qualified-name. In the first two cases, if the type of the expression is "T," the type of the result is "pointer to T." In particular, the address of an object of type const T has type const T\*; volatile is handled similarly. For a qualified-name, if the member is not static and of type "T" in class "C", the type of the result is "pointer to member of C of type T." For a static member of type T, the type is plain "pointer to T." The address of an overloaded function (§13) can only be taken in an initialization or assignment where the left hand side uniquely determines which version of the overloaded function is referred to (§13.3).

The operand of the unary + operator must have arithmetic or pointer type and the result is the value of the argument. Integral promotion is performed on integral operands. The type of the result is the type of the promoted operand.

The operand of the unary – operator must have arithmetic type and the result is the negation of its operand. Integral promotion is performed on integral operands. The negative of an unsigned quantity is computed by subtracting its value from  $2^n$ , where n is the number of bits in the promoted operand. The type of the result is the type of the promoted operand.

The operand of the logical negation operator! must have arithmetic type or be a pointer; its value is 1 if the value of its operand is 0 and 0 if the value of its operand is non-zero. The type of the result is int.

The operand of ~ must have integral type; the result is the 1's complement of its operand. Integral promotions are performed. The type of the result is the type of the promoted operand.

#### 5.3.1 Increment and Decrement

The operand of prefix ++ is incremented by 1. The operand must be a modifiable lvalue. The value is the new value of the operand; it is an Ivalue. The expression ++x is equivalent to x+=1. See the discussions of addition (§5.7) and assignment operators (§5.17) for information on conversions.

The operand of prefix -- is decremented analogously to the prefix ++ operator.

#### 5.3.2 Sizeof

The sizeof operator yields the size, in bytes, of its operand. The operand is either an expression, which is not evaluated, or a parenthesized type name. The size of operator may not be applied to a function, a bit-field, or an undefined class. A byte is undefined by the language except in terms of the value of sizeof; sizeof (char) is 1.

When applied to a reference, the result is the size of the referenced object. When applied to a class, the result is the number of bytes in an object of that class including any padding required for placing such objects in an array. The size of any class or class object is larger than zero. When applied to an array, the result is the total number of bytes in the array. This implies that the size of an array of n elements is n times the size of an element. It is illegal to take the size of an array with an unspecified dimension.

The result is a constant of type size\_t, an implementation dependent unsigned integral type defined in the standard header < stddef.h>.

#### 5.3.3 New

The new operator attempts to create an object of the type-name (§8.1) to which it is applied. This type must be an object type; functions cannot be allocated this way, though pointers to functions can.

```
allocation-expression:
         :: opt new placementopt restricted-type-name initializer opt
         :: opt new placementopt ( type-name ) initializeropt
placement:
         ( expression-list )
restricted-type-name:
        type-specifiers restricted-declaratorout
restricted-declarator:
        ptr-operator restricted-declaratorout
        restricted-declarator [ expressionout ]
```

The lifetime of an object created by new is not restricted to the scope in which it is created. The new operator returns a pointer to the object it created. When that object is an array, a pointer to its initial element is returned. For example, both new int and new int [10] return an int\* and the type of new int[i][10] is int (\*)[10]. Where an array type (§10) is specified all array dimensions but the first must be constant expressions (§5.19) with positive

values. The first array dimension can be a general expression even when the type-name is used (despite the fact that array dimensions in type-names are generally restricted to constant-expressions (§5.19)).

The new operator will call the function operator new() to obtain storage. A first argument of sizeof(T) is supplied when allocating an object of type T. The placement syntax can be used to supply additional arguments. For example, new T results in a call of operator new(sizeof(T)) and new(2, f) T results in a call operator new(sizeof(T), 2, f).

The placement syntax can only be used provided an operatornew() with suitable argument types (§13.2) has been declared.

When an object of a non-class type (including arrays of class objects) is created with operator new, the global ::operator new() is used. When an object of a class T is created with operator new() is used if it exists (using the usual lookup rules for finding members of a class and its base classes; §10.1.1); otherwise the global ::operator new() is used. Using ::new ensures that the global ::operator new() is used even if T::operator new() exists.

An initializer (§8.4) of the form (expression-list<sub>opt</sub>) may be supplied in an allocation-expression. For objects of classes with a constructor (§12.1) this argument list will be used in a constructor call; otherwise the initializer must be of the form (expression) and will be used to initialize the object.

If a class has a constructor an object of it can only be created by new if suitable arguments are provided or if the class has a constructor that can be called without arguments.

No initializers can be specified for arrays. Arrays of objects of a class with constructors can only be created by operator new if the class has a default constructor (§12.1). In that case, the default constructor will be called for each element of the array.

Initialization is done only if the value returned by operator new() is non-zero. If the value returned by the operator new() is 0 (the null pointer) the value of the expression is 0.

In a restricted-type-name used as the operand for new, parentheses may not be used. This implies that

```
new int(*[10])(); // error is an error because the binding is

(new int) (*[10])(); // error
```

Objects of general type can be expressed using the explicitly parenthesized version of the new operator. For example:

```
new (int (*[10])());
```

allocates an array of 10 pointers to functions (taking no argument and returning int).

When parsing the restricted-type in an allocation-expression expressions the longest sequence of restricted-declarators is used. This prevents ambiguities between declarator operators \*, and [] and their expression counterparts. For example,

#### 5.3.4 Delete

The delete operator destroys an object created by the new operator.

deallocation-expression:

:: opt delete cast-expression

:: opt delete [ expression ] cast-expression

The result has type void. The operand of delete must be a pointer returned by new. The effect of applying delete to a pointer not obtained from the new operator without a placement specification is undefined and usually harmful. However, deleting a pointer with the value zero is guaranteed to be harmless.

The effect of accessing a deleted object is undefined and the deletion of an object may change its value. Furthermore, if the expression denoting the object in a delete expression is a modifiable lyalue its value is undefined after the deletion.

The delete operator will invoke the destructor (if any §12.4) for the object pointed to.

To free the store pointed to, the delete operator will call the function operator delete(). For objects of a non-class type (including arrays of class objects), the global ::operator delete() is used. For an object of a class T, T::operator delete() is used if it exists (using the usual lookup rules for finding members of a class and its base classes; §10.1.1); otherwise the global ::operator delete() is used. Using ::delete ensures that the global ::operator delete() is used even if T::operator delete() exists.

The form

delete [ expression ] cast-expression

is used to delete arrays. The second expression points to an array and the first expression gives the number of elements of that array (see §12.4). The destructors (if any) for the objects pointed to will be invoked.

# 5.4 Explicit Type Conversion

cast-expression:

unary-expression (type-name) cast-expression

An explicit type conversion can be expressed either using functional notation (§5.2.3) or the cast notation. The cast notation is needed to express conversion to a type that does not have a simple-type-name.

Any type that can be converted to another by a standard conversion (§4) can also be converted by explicit conversion and the meaning is the same.

A pointer may be explicitly converted to any integral type large enough to hold it. The mapping function is implementation dependent, but is intended to be unsurprising to those who know the addressing structure of the underlying machine.

A value of integral type may be explicitly converted to a pointer. A pointer converted to an integer of sufficient size (if any such exists on the implementation) and back to the same pointer type will have its original value; mappings between pointers and integers are otherwise implementation dependent.

A pointer to one object type may be explicitly converted to a pointer to another object type (subject to the restrictions mentioned in this section). The resulting pointer may cause addressing exceptions upon use if the subject pointer does not refer to an object suitably aligned in storage. It is guaranteed that a pointer to an object of a given size may be converted to a pointer to an object of the same or smaller size and back again without change. Different machines may differ in the number of bits in pointers and in alignment requirements for objects. Aggregates are aligned on the strictest boundary required by any of their constituents.

A pointer to a class B may be explicitly converted to a pointer to a class D that has B as a direct or indirect base class provided an unambiguous conversion from D to B exists (§4.6, §10.1.1) and provided that B is not a virtual base class (§10.1). Such a cast from a base to a derived class assumes that the object of the base class is a sub-object of an object of the derived class; the resulting pointer points to the enclosing object of the derived class. If the object of the base class is not a sub-object of an object of the derived class the cast may cause an exception. The null pointer (0) is converted into itself.

An object may be explicitly converted to a reference type X& if a pointer to that object may be explicitly converted to an X\*. Constructors or conversion functions are not called as the result of a cast to a reference. Conversion of a reference to a base class to a reference to a derived class is handled similarly to the conversion of a pointer to a base class to a pointer to a derived class with respect to ambiguity, virtual classes, etc.

The result of a cast to a reference type is an Ivalue; the results of other casts are not. Operations performed on the result of a pointer or reference refer to the same object as the original (uncast) expression.

A pointer to function may be explicitly converted to a pointer to an object type provided the object pointer type has sufficient bits to hold the function pointer. A pointer to an object type may be explicitly converted to a pointer to function provided the function pointer type has sufficient bits to hold the object pointer. In both cases, the resulting pointer may cause addressing exceptions upon use if the subject pointer does not refer to suitable storage.

A pointer to function may be explicitly converted to a pointer to a function of a different type. The effect of calling a function through a pointer to a function type that differs from the type used in the definition of the function is undefined.

An object may be converted to a class object (only) if an appropriate constructor or conversion operator has been declared (§12.3).

A pointer to member may be explicitly converted into a different pointer to member type when the two types are both pointers to members of the same class or when the two types are pointers to member functions of classes derived from each other.

A pointer to an object of a const type can be cast into a pointer to a non-const. The resulting pointer will refer to the original object. An object of a const type or a reference to an object of a const type can be cast into a reference to a non-const. The resulting reference will refer to the original object. The result of attempting to modify that object through such a pointer or reference is undefined.

# 5.5 Pointer-to-Member Operators

The pointer-to-member operators ->\* and .\* group left-to-right.

pm-expression:

cast-expression
pm-expression .\* cast-expression
pm-expression ->\* cast-expression

The binary operator .\* binds its second operand, which must be of type "pointer to member of class T" to its first operand, which must be of class T or of a class publicly derived from class T. The result is an object or a function of the type specified by the second operand.

The binary operator ->\* binds its second operand, which must be of type "pointer to member of T" to its first operand, which must be of type "pointer to T" or "pointer to class publicly derived from T." The result is an object or a function of the type specified by the second operand.

If the result of .\* or ->\* is a function, then that result can be used only as the operand for the function call operator (). For example,

```
(ptr_to_obj->*ptr_to_mfct)(10);
```

calls the member function denoted by ptr\_to\_mfct for the object pointed to by ptr\_to\_obj.

### 5.6 Multiplicative Operators

The multiplicative operators \*, /, and % group left-to-right.

```
multiplicative-expression:

pm-expression

multiplicative-expression * pm-expression

multiplicative-expression / pm-expression

multiplicative-expression % pm-expression
```

The operands of \* and / must have arithmetic type; the operands of % must have integral type. The usual arithmetic conversions (§4.5) are performed on the operands and determine the type of the result.

The binary \* operator indicates multiplication.

The binary / operator yields the quotient, and the binary % operator yields the remainder from the division of the first expression by the second. If the second operand is 0 the result is undefined; otherwise (a/b)\*b + a%b is equal to a. If both operands are non-negative then the remainder is non-negative; if not, the sign of the remainder is implementation dependent.

### 5.7 Additive Operators

The additive operators + and - group left-to-right. The usual arithmetic conversions (§4.5) are performed for operands of arithmetic type.

```
additive-expression:

multiplicative-expression

additive-expression + multiplicative-expression

additive-expression - multiplicative-expression
```

The result of the + operator is the sum of the operands. A pointer to an object in an array and a value of any integral type may be added. The result is a pointer of the same type as the original pointer, which points to another object in the same array, appropriately offset from the original object. Thus if P is a pointer to an object in an array, the expression P+1 is a pointer to the next object in the array. If the resulting pointer points outside the bounds of the array, except at the first location beyond the high end of the array, the result is undefined.

The result of the - operator is the difference of the operands. A value of any integral type may be subtracted from a pointer, and then the same conversions apply as for addition.

No further type combinations are allowed for pointers.

If two pointers to objects of the same type are subtracted, the result is a signed integral value representing the number of objects separating the pointed-to objects. Pointers to successive elements of an array differ by 1. The type of the result is implementation dependent, but is defined as ptrdiff\_t in the standard header <stddef.h>. The value is undefined unless the pointers point to elements of the same array or to the first location beyond the high end of the array.

# 5.8 Shift Operators

The shift operators << and >> group left-to-right.

```
shift-expression:

additive-expression

shift-expression << additive-expression

shift-expression >> additive-expression
```

The operands must be of integral type and integral promotions are performed. The type of the result is that of the left operand. The result is undefined if the right operand is negative, or greater than or equal to the length in bits of the promoted left operand. The value of E1 << E2 is E1 (interpreted as a bit pattern) left-shifted E2 bits; vacated bits are 0-filled. The value of E1 >> E2 is E1 right-shifted E2 bit positions. The right shift is guaranteed to be logical (0-fill) if E1 has an unsigned type or if it has a non-negative value; otherwise the result is implementation dependent.

### 5.9 Relational Operators

The relational operators group left-to-right, but this fact is not very useful; a < b < c means (a < b) < c and not (a < b) & & (b < c).

```
relational-expression:
    shift-expression
    relational-expression < shift-expression
    relational-expression > shift-expression
    relational-expression <= shift-expression
    relational-expression >= shift-expression
```

The operators < (less than), > (greater than), <= (less than or equal to), and >= (greater than or equal to) all yield 0 if the specified relation is false and 1 if it is true. The type of the result is int.

The usual arithmetic conversions are performed on arithmetic operands. Pointer conversions are performed on pointer operands. This implies that any pointer may be compared to a constant expression evaluating to 0 and any pointer can be compared to a pointer of type void\* (in the latter case the pointer is first converted to void\*). Pointers to objects or functions of the same type (after pointer conversions) may be compared; the result depends on the relative positions of the pointed-to objects or functions in the address space.

Two pointers to the same object compare equal. If two pointers point to non-static members of the same object, the pointer to the member defined last compares higher provided the two members are defined using the same access-specifier (§11.1) and provided their class is not a union. If two pointers point to non-static members of the same union, they compare equal. If two pointers point to elements of the same array or one beyond the end of the array, the pointer to the object with the highest subscript compares higher. Other pointer comparisons are implementation dependent.

### 5.10 Equality Operators

```
equality-expression:

relational-expression

equality-expression == relational-expression

equality-expression != relational-expression
```

The == (equal to) and the != (not equal to) operators are exactly analogous to the relational operators except for their lower precedence. (Thus a < b == c < d is 1 whenever a < b and c < d have the same truth-value.)

In addition, pointers to members of the same type may be compared. Pointer to member conversions (§4.8) are performed. A pointer to member may be compared to a constant expression that evaluates to 0.

### 5.11 Bitwise AND Operator

and-expression:

equality-expression and-expression & equality-expression

The usual arithmetic conversions are performed; the result is the bitwise AND function of the operands. The operator applies only to integral operands.

### 5.12 Bitwise Exclusive OR Operator

exclusive-or-expression: and-expression exclusive-or-expression ^ and-expression

The usual arithmetic conversions are performed; the result is the bitwise exclusive OR function of the operands. The operator applies only to integral operands.

### 5.13 Bitwise Inclusive OR Operator

inclusive-or-expression: exclusive-or-expression inclusive-or-expression | exclusive-or-expression

The usual arithmetic conversions are performed; the result is the bitwise inclusive OR function of its operands. The operator applies only to integral operands.

### 5.14 Logical AND Operator

logical-and-expression: inclusive-or-expression logical-and-expression && inclusive-or-expression

The && operator groups left-to-right. It returns 1 if both its operands are non-zero, 0 otherwise. Unlike &, && guarantees left-to-right evaluation; moreover the second operand is not evaluated if the first operand evaluates to 0.

The operands need not have the same type, but each must have arithmetic type or be a pointer. The result is an int. All side effects of the first expression happen before the second expression is evaluated.

### 5.15 Logical OR Operator

logical-or-expression: logical-and-expression logical-or-expression | | logical-and-expression

The || operator groups left-to-right. It returns 1 if either of its operands is non-zero, and 0 otherwise. Unlike |, | | guarantees left-to-right evaluation; moreover, the second operand is not evaluated if the first operand evaluates to non-zero.

The operands need not have the same type, but each must have arithmetic type or be a pointer. The result is an int. All side effects of the first expression happen before the second expression is evaluated.

# 5.16 Conditional Operator

Conditional expressions group right-to-left. The first expression must have arithmetic type or be a pointer type. It is evaluated and if it is non-zero, the result of the conditional expression is the value of the second expression, otherwise that of the third expression. All side effects of the first expression happen before the second or third expression is evaluated.

If both the second and the third expressions are of arithmetic type, the usual arithmetic conversions are performed to bring them to a common type. Otherwise, if both the second and the third expressions are either a pointer or a constant expression that evaluates to 0, pointer conversions are performed to bring them to a common type. Otherwise, if both the second and the third expressions are references, reference conversions are performed to bring them to a common type. Otherwise, if both the second and the third expressions are void, the common type is void. Otherwise the expression is illegal. The result has the common type; only one of the second and third expressions is evaluated. The result is an Ivalue if the second and the third operand are of the same type and both are Ivalues.

# 5.17 Assignment Operators

There are a number of assignment operators, all of which group right-to-left. All require a modifiable lvalue as their left operand, and the type of an assignment expression is that of its left operand. The result of the assignment operation is the value stored in the left operand after the assignment has taken place; the result is an lvalue.

In simple assignment (=), the value of the expression replaces that of the object referred to by the left operand. If both operands have arithmetic type, the right operand is converted to the type of the left preparatory to the assignment. There is no implicit conversion to an enumeration (§7.2) so if the right operand is of an enumeration type the left operand must be of the same type. If the left operand has pointer type, the right operand must be of pointer type or a constant expression that evaluates to 0; the right operand is converted to the type of

-= >>= <<= &= ^= |=

the left before the assignment.

A pointer of type T\*const can be assigned to a pointer of type T\*, but the reverse assignment is illegal (§7.1.6). Objects of types const T and volatile T can be assigned to "plain" T lvalues and to lvalues of type volatile T; see also (§8.4).

If the left operand has pointer to member type, the right operand must be of pointer to member type or a constant expression that evaluates to 0; the right operand is converted to the type of the left before the assignment.

Assignment to objects of a class (§9) x is defined by the function X::operator=() (§13.4.3). Unless the user defines an X::operator=(), the default version is used for assignment (§12.8). This implies that an object of a class derived from X (directly or indirectly) by public derivation can be assigned to an X.

A pointer to a member of class B may be assigned to a pointer to a member of class D of the same type provided D is derived from B (directly or indirectly) by public derivation.

Assignment to an object of type "reference to T" assigns to the object of type T denoted by the reference.

The behavior of an expression of the form E1 op = E2 is equivalent to E1 = E1 op (E2); except that E1 is evaluated only once. In += and -=, the left operand may be a pointer, in which case the (integral) right operand is converted as explained in §5.7; all right operands and all non-pointer left operands must have arithmetic type.

Note that for class objects assignment is not in general the same as initialization (§8.4, §12.1, §12.6, §12.8).

# 5.18 Comma Operator

The comma operator groups left-to-right.

expression:

assignment-expression expression, assignment-expression

A pair of expressions separated by a comma is evaluated left-to-right and the value of the left expression is discarded. All side effects of the left expression are performed before the evaluation of the right expression. The type and value of the result are the type and value of the right operand; the result is an Ivalue if its right operand is.

In contexts where comma is given a special meaning, for example, in lists of actual arguments to functions (§5.2.2) and lists of initializers (§8.4), the comma operator as described in this section can only appear in parentheses; for example,

$$f(a, (t=3, t+2), c)$$

has three arguments, the second of which has the value 5.

# 5.19 Constant Expressions

In several places, C++ requires expressions that evaluate to an integral constant: as array bounds (§8.2.4), as case expressions (§6.4.2), as bit-field lengths (§9.6), and as enumerator initializers (§7.2).

constant-expression: conditional-expression

A constant-expression can involve only literals (§2.5), enumerators, const values of integral types initialized with constant expressions (§8.4), and sizeof expressions. Floating constants (§2.5.3) must be cast to integral types. Only type conversions to integral types may be used. In particular, except in sizeof expressions, functions, class objects, pointers, and references cannot be used.

## 6. Statements

Except as indicated, statements are executed in sequence.

statement:

labeled-statement expression-statement compound-statement selection-statement iteration-statement jump-statement

dstatement:

statement declaration-statement

### 6.1 Labeled Statement

A statement may be labeled.

labeled-statement:

identifier : dstatement

case constant-expression: statement

default : statement

An identifier label declares the identifier. The only use of an identifier label is as a target of a goto. The scope of a label is the current function. Labels cannot be redeclared within a function. A label can be used in a goto statement before its definition. Labels have their own name space and do not interfere with other identifiers.

Case labels and default labels may occur only in switch statements.

# 6.2 Expression Statement

Most statements are expression statements, which have the form

```
expression-statement:
expression<sub>opt</sub>;
```

Usually expression statements are assignments or function calls. All side effects from an expression statement are completed before the next statement is executed. An expression statement with the expression missing is called a null statement; it is useful to carry a label just before the } of a compound statement and to supply a null body to an iteration statement such as while.

# 6.3 Compound Statement, or Block

So that several statements can be used where one is expected, the compound statement (also, and equivalently, called "block") is provided:

compound-statement:
{ statement-list<sub>opt</sub> }
statement-list:
 dstatement
 statement-list dstatement

Note that a declaration is a dstatement (§6.7).

### 6.4 Selection Statements

Selection statements choose one of several flows of control.

selection-statement:

```
if (expression) statement
if (expression) statement else statement
switch (expression) statement
```

#### 6.4.1 If Statements

The expression must be of arithmetic or pointer type or of a class type for which an unambiguous conversion to arithmetic or pointer type exists (§12.3).

The expression is evaluated and if it is non-zero, the first substatement is executed. If else is used, the second substatement is executed if the expression is zero. The "else" ambiguity is resolved by connecting an else with the last encountered else-less if.

#### 6.4.2 Switch Statement

The switch statement causes control to be transferred to one of several statements depending on the value of an expression.

The expression must be of integral type or of a class type for which an unambiguous conversion to integral type exists (§12.3). Integral promotion is performed. Any statement within the statement may be labeled with one or more case labels as follows:

```
case constant-expression:
```

where the constant-expression (§5.19) is converted to the promoted type of the switch expression. No two of the case constants in the same switch may have the same value.

There may also be at most one label of the form

```
default :
```

within a switch statement.

Switch statements may be nested; a case or default label is associated with the smallest switch enclosing it.

When the switch statement is executed, its expression is evaluated and compared with each case constant. If one of the case constants is equal to the value of the expression, control is passed to the statement following the matched case label. If no case constant matches the expression, and if there is a default label, control passes to the labeled statement. If no case matches and if there is no default then none of the statements in the switch is executed.

case and default labels in themselves do not alter the flow of control, which continues unimpeded across such labels. To exit from a switch, see break, §6.6.1.

Usually the statement that is the subject of a switch is compound. Declarations may appear in this statement. However, it is illegal to jump past a declaration with an explicit or implicit initializer unless the declaration is in an inner block that is not entered (that is, completely bypassed by the transfer of control). This implies that declarations that contain explicit or implicit initializers must be contained in an inner block.

### 6.5 Iteration Statements

Iteration statements specify looping.

```
iteration-statement:
    while (expression) statement
    do statement while (expression);
    for (for-init-statement expressionopt; expressionopt) statement

for-init-statement:
    expression-statement
    declaration-statement
```

Note that a for-init-statement ends with a semicolon.

#### 6.5.1 While Statement

In the while statement the substatement is executed repeatedly until the value of the expression becomes zero. The test takes place before each execution of the statement.

The expression must be of arithmetic or pointer type or of a class type for which an unambiguous conversion to arithmetic or pointer type exists (§12.3).

#### 6.5.2 Do statement

In the do statement the substatement is executed repeatedly until the value of the expression becomes zero. The test takes place after each execution of the statement.

The expression must be of arithmetic or pointer type or of a class type for which an unambiguous conversion to arithmetic or pointer type exists (§12.3).

#### 6.5.3 For Statement

```
The for statement

for ( for-init-statement expression-1<sub>opt</sub> ; expression-2<sub>opt</sub> ) statement
is equivalent to

for-init-statement
while ( expression-1 ) {
    statement
    expression-2 ;
```

except that a continue in statement will execute expression-2 before re-evaluating expression-1. Thus the first statement specifies initialization for the loop; the first expression specifies a test, made before each iteration, such that the loop is exited when the expression becomes zero; the second expression often specifies incrementing that is done after each iteration. The first expression must have arithmetic or pointer type or a class type for which an unambiguous conversion to arithmetic or pointer type exists (§12.3).

Either or both of the expressions may be dropped. A missing expression-1 makes the implied while clause equivalent to while (1).

Note that if for-init-statement is a declaration, the scope of the names declared extends to the end of the block enclosing the for-statement.

A for-statement containing a declaration in its for-init-statement may not be the statement after an if, else, switch, while, do, or for. This restriction follows from the rule against jumping past initialized declarations (§6.6).

# 6.6 Jump Statements

Jump statements unconditionally transfer control.

```
jump-statement:
       break ;
       continue ;
       return expressionopt ;
       goto identifier;
```

On exit from a scope (however accomplished), destructors are called for all constructed class objects in that scope that have not yet been destroyed. This applies to both explicitly declared objects and temporaries (§12.2).

#### 6.6.1 Break Statement

The break statement must occur in an iteration-statement or a switch statement and causes termination of the smallest enclosing iteration-statement or switch statement; control passes to the statement following the terminated statement, if any.

#### 6.6.2 Continue Statement

The continue statement must occur in an iteration-statement and causes control to pass to the loop-continuation portion of the smallest enclosing iteration-statement, that is, to the end of the loop. More precisely, in each of the statements

```
while (...) {
            do { for (...) {
 . . .
              . . .
             contin: ;
contin: ;
                            contin: ;
             } while (...);
```

a continue not contained in an enclosed iteration statement is equivalent to goto contin.

#### 6.6.3 Return Statement

A function returns to its caller by means of the return statement. A return statement without an expression can be used only in functions that do not return a value, that is, a function with the return value type void or a constructor (§12.1) or a destructor (§12.4). A return statement with an expression can be used only in functions returning a value; the value of the expression is returned to the caller of the function. If required, the expression is converted, as in an initialization, to the return type of the function in which it appears. This may involve the construction and copy of a temporary object (§12.2). Flowing off the end of a function is equivalent to a return with no value; this is illegal in a value-returning function.

#### 6.6.4 Goto Statement

The goto statement unconditionally transfers control to the statement labeled by the identifier. The identifier must be a label (§6.1) located in the current function. It is illegal to jump past a declaration with an explicit or implicit initializer unless the declaration is in an inner block that is not entered (that is, completely bypassed by the transfer of control).

### 6.7 Declaration Statement

A declaration statement is used to introduce a new identifier into a block; it has the form

declaration-statement: declaration

If an identifier introduced by a declaration was previously declared in an outer block, the outer declaration is hidden for the remainder of the block, after which it resumes its force.

Any initializations of auto or register variables are done each time their declaration-statement is executed. It is possible to transfer into a block, but not in a way that causes initializations not to be done (§6.6). Destruction of local variables declared in the block is done upon exit from the block (§6.6).

Initialization of an object with storage class static (§7.1.1) is done the first time control passes through its declaration (only). The destructor for a local static object will be executed if and only if the variable was constructed.

# 6.8 Ambiguity Resolution

There is an ambiguity in the grammar involving expression-statements and declarations: An expression-statement with a "function style" explicit type conversion (§5.2.3) as its leftmost sub-expression can be indistinguishable from a declaration where the first declarator starts with a (. In those cases the statement is a declaration.

To disambiguate, the whole *statement* may have to be examined to determine if it is an *expression-statement* or a *declaration*. This disambiguates many examples. For example, assume T is a *simple-type-name* (§7.1.6):

```
T(a) ->m = 7;  // expression-statement
T(a) ++;  // expression-statement
T(a,5) << c;  // expression-statement
T(*d) (double(3));  // expression-statement
T(*e) (int);  // declaration
T(f)[];  // declaration
T(g) = { 1, 2 };  // declaration</pre>
```

The remaining cases are declarations. For example:

```
T(a); // declaration
T(*b)(); // declaration
T(c)=7; // declaration
T(d),e,f=3; // declaration
T(g)(h,2); // declaration
```

The disambiguation is purely syntactic; that is, the meaning of the names, beyond whether they are *type-names* or not, is not used in the disambiguation.

Note that a simple lexical lookahead can help a parser disambiguate most cases. Consider analyzing a *statement* consisting of a sequence of tokens:

```
type-name ( d-or-e ) tail
```

Here, d-or-e must be a declarator, an expression, or both for the statement to be legal. This implies that tail must be a semicolon, something that can follow a parenthesized declarator or something that can follow a parenthesized expression, that is, an initializer, const, volatile, (or [ or a postfix or infix operator.

A user can explicitly disambiguate cases that appear obscure. For example:

```
void f()
{
    auto int(*p)();  // explicitly declaration
    (void) int(*p)();  // explicitly expression-statement
    0,int(*p)();  // explicitly expression-statement
    (int(*p)());  // explicitly expression-statement
    int(*p)();  // resolved to declaration
}
```

A slightly different ambiguity between *expression-statements* and *declarations* is resolved by requiring a *type-name* for function declarations within a block (§6.3). For example:

```
void g()
{
    int f();  // declaration
    int a;  // declaration
    f();  // expression-statement
    a;  // expression-statement
}
```

## 7. Declarations

Declarations specify the interpretation given to each identifier; they do not necessarily reserve storage associated with the identifier (§3.1). Declarations have the form

declaration: decl-specifiersopt declarator-listopt; asm-declaration function-definition linkage-specification

The declarators in the declarator-list (§8) contain the identifiers being declared. Only in function definitions (§8.3) and function declarations may the decl-specifiers be omitted. Only when declaring a class (§9) or enumeration (§7.2), that is, when the decl-specifier is a classspecifier or enum-specifier, may the declarator-list be empty. asm-declarations are described in §7.3, and linkage-specifications in §7.4. A declaration occurs in a scope (§3.2); the scope rules are summarized in §10.4.

# 7.1 Specifiers

The specifiers that can be used in a declaration are:

```
decl-specifier:
         storage-class-specifier
         type-specifier
         fct-specifier
         template-specifier
         friend
         typedef
decl-specifiers:
         decl-specifiers out decl-specifier
```

The longest sequence of decl-specifiers that could possibly be a type name is taken as the declspecifiers of a declaration. The sequence must be self-consistent as described below. For example,

```
typedef char* Pc;
                         // error: name missing
static Pc;
```

Here, the declaration static Pc is illegal because no name was specified for the static variable of type Pc. To get a variable of type int called Pc, the type-specifier int must be present to indicate that the typedef-name Pc is the name being (re)declared, rather than being part of the decl-specifier sequence. For example,

```
// void f(char*const)
void f(const Pc);
void g(const int Pc); // void g(const int)
```

Note that since signed, unsigned, long, and short by default imply int, a typedef-name appearing after one of those specifiers must be the name being (re)declared. For example:

```
// void h(unsigned int)
void h (unsigned Pc);
void k(unsigned int Pc); // void k(unsigned int)
```

# 7.1.1 Storage Class Specifiers

The "storage class" specifiers are:

```
storage-class-specifier:
auto
register
static
extern
```

The auto or register specifiers can be applied only to names of objects declared in a block (§6.3) and for formal arguments (§8.3). The auto declarator is always redundant and not often used; one use of auto is explicitly to distinguish a declaration-statement from an expression-statement (§6.2).

A register declaration is an auto declaration, together with a hint to the compiler that the variables declared will be heavily used. The hint may be ignored and in most implementations it will be ignored if the address of the variable is taken.

An object declaration is a definition unless it contains the extern specifier and no initializer (§3.1). A definition causes the appropriate amount of storage to be reserved and any appropriate initialization (§8.4) to be done.

The static and extern specifiers can be applied only to names of objects or functions. There can be no static function declarations within a block, nor any static or extern formal arguments. Static class members are described in (§9.4); extern cannot be used for class members.

A name specified static has internal linkage. Functions declared inline and objects declared const have internal linkage unless they have previously been given external linkage. A name specified extern has external linkage unless it has previously been given internal linkage. A file scope name without a storage-class-specifier has external linkage unless it has previously been given internal linkage and provided it is not declared const or inline. All linkage specifications for a name must agree. For example:

```
static char* f(); // f() has internal linkage
char* f() // f() still has internal linkage
      { /* ... */ }
             // g() has external linkage
static char* g() // error: inconsistent linkage specifications
      { /* ... */ }
static int a; // 'a' has internal linkage
int a;
                 // error: two definitions
static int b; // 'b' has internal linkage
                // 'b' still has internal linkage
extern int b;
                // 'c' has external linkage
int c;
static int c; // error: inconsistent linkage specifications
               // 'd' has external linkage
// error: inconsistent linkage specifications
extern d;
static int b;
```

# 7.1.2 Function Specifiers

Some specifiers can only be used in function declarations:

```
fct-specifier:
inline
virtual
```

The inline specifier gives the function default internal linkage (§3.3); it is also a hint to the compiler that inline substitution of the function body is to be preferred to the usual function call implementation. The hint may be ignored. A function (§5.2.2, §8.2.5) defined within the declaration of a class is inline by default.

A global inline function may explicitly be given external linkage provided it is not called between the extern declaration and the inline definition. For example:

```
extern f();
extern g();

h() { return f(); }

inline f() { /* ... */ } // error
inline g() { /* ... */ } // ok
```

Here g() has external linkage but can be inlined in the (one) source file where its definition appears.

A class member function need not be declared inline in the class declaration to be inline. Where no inline specifier is used, linkage will be external unless an inline definition appears before the first call.

The virtual specifier may be used only in declarations of non-static class member functions within a class declaration; see §10.2.

# 7.1.3 The typedef Specifier

Declarations containing the decl-specifier typedef declare identifiers that can be used later for naming fundamental or derived types. The typedef specifier may not be used in a fct-definition (§8.3).

```
typedef-name:
identifier
```

Within the scope (§3.2) of a typedef declaration, each identifier appearing as part of any declarator therein becomes syntactically equivalent to a keyword and names the type associated with the identifier in the way described in §8. A typedef-name is thus a synonym for

another type. A typedef-name does not introduce a new type the way a class declaration (§9.1) does. For example, after

```
typedef int MILES, *KLICKSP;
```

the constructions

```
MILES distance;
extern KLICKSP metricp;
```

are all legal declarations; the type of distance is int; that of metricp is "pointer to int."

A typedef may be used to re-define a name to refer to the type it already referred to — even in the scope where the type was originally declared. For example,

```
typedef struct s { /* ... */ } s;
typedef int I;
typedef int I;
typedef I I;
```

A typedef may be not be used to re-define a name of a type declared in the same scope to refer to a different type. For example,

```
class complex { /* ... */ };
typedef int complex; // error: redefinition of 'complex'
```

A typedef-name that names a class is a class-name (§9.1).

### 7.1.4 The template Specifier

The template specifier is used to specify families of types or functions; see §14.

## 7.1.5 The friend Specifier

The friend specifier is used to specify access to class members; see §11.4.

# 7.1.6 Type Specifiers

The type-specifiers are:

```
type-specifier:

simple-type-name
class-specifier
enum-specifier
elaborated-type-specifier
const
volatile
```

The words const and volatile may be added to any legal type-specifier in the declaration of an object. Otherwise, at most one type-specifier may be given in a declaration. A const object may be initialized, but its value may not be changed thereafter. Unless explicitly declared extern, a const object does not have external linkage and must be initialized (§8.4; §12.1). An integer const initialized by a constant expression may be used in constant expressions (§5.19). Each element of a const array is const and each member of a const class object is const (§9.3.1).

There are no implementation-independent semantics for volatile objects; volatile is a hint to the compiler to avoid aggressive optimization involving the object because the value of the object may be changed by means undetectable by a compiler. Each element of a volatile array is volatile and each member of a volatile class object is volatile (§9.3.1).

If the type-specifier is missing from a declaration, it is taken to be int.

```
simple-type-name:
    class-name
    typedef-name
    char
    short
    int
    long
    signed
    unsigned
    float
    double
    void
```

At most one of the words long or short may be specified together with int. Either may appear alone, in which case int is understood. The word long may be mentioned together with double. At most one of the words signed and unsigned may be specified together with char, short, int, or long. Either may appear alone, in which case int is understood. The signed specifier is used to force char objects and bit-fields to be signed; it is redundant with other integral types.

class-specifiers and enum-specifiers are discussed in §9 and §7.2, respectively.

```
elaborated-type-specifier:
    class-key class-name
    class-key identifier
    enum enum-name

class-key:
    class
    struct
    union
```

If an identifier is specified, the elaborated-type-specifier declares it to be a class-name; see §9.1.

If defined, a name declared using the union specifier must be defined as a union. If defined, a name declared using the class specifier must be defined using the class or struct specifier. If defined, a name declared using the struct specifier must be defined using the class or struct specifier.

### 7.2 Enumeration Declarations

An enumeration is a distinct integral type (§3.6.1) with named constants. Its name becomes an enum-name, that is, a reserved word within its scope.

```
enum-name:
    identifier

enum-specifier:
    enum identifieropt { enum-listopt }

enum-list:
    enumerator
    enum-list , enumerator

enumerator:
    identifier
    identifier = constant-expression
```

The identifiers in an enum-list are declared as constants, and may appear wherever constants

are required. If no enumerators with = appear, then the values of the corresponding constants begin at 0 and increase by 1 as the declaration is read from left to right. An enumerator with = gives the associated identifier the value indicated; subsequent identifiers without initializers continue the progression from the assigned value. The value of an enumerator must be an int or a value that can be promoted to int by integral promotion (§4.1).

The names of enumerators must be distinct from those of ordinary variables and other enumerators in the same scope. The values of the enumerators need not be distinct. An enumerator is considered defined immediately after it and its initializer, if any, has been seen. For example,

```
enum { a, b, c=0 };
enum { d, e, f=e+2 };
```

defines a, c, and d to be 0, b and e to be 1, and f to be 3.

Each enumeration defines an integral type that is different from all other integral types. The type of an enumerator is its enumeration. The value of an enumerator or an object of an enumeration type is converted to an integer by integral promotion (§4.1). For example,

```
enum color { red, yellow, green=20, blue };
color col = red;
color* cp = &col;
if (*cp == blue) // ...
```

makes color an integral type describing various colors, and then declares col as an object of that type, and cp as a pointer to an object of that type. The possible values of an object of type color are red, yellow, green, blue; these values can be converted to the int values 0, 1, 20, and 21. Since enumerations are distinct types, objects of type color may be assigned only values of type color. For example:

See also §B.3.

Enumerators defined in a class (§9) are in the scope of that class and can only be referred to outside member functions of that class by explicit qualification with the class name (§5.1). However, the name of the enumeration itself is not local to the class (§9.7). For example:

## 7.3 Asm Declarations

An asm declaration has the form

```
asm-declaration:
asm ( string ) ;
```

The meaning of an asm declaration is implementation dependent. Typically it is used to pass information through the compiler to an assembler.

# 7.4 Linkage Specifications

Linkage (§3.3) to non-C++ code fragments can be achieved using a linkage-specification:

```
linkage-specification:

extern string { declaration-listopt }

extern string declaration

declaration-list:

declaration

declaration-list declaration
```

The string is used to indicate what kind of linkage is required. The meaning of the string is implementation dependent. Linkage to a function written in the C programming language, "C", and linkage to a C++ function, "C++", must be provided by every implementation. Default linkage is "C++". For example,

```
complex sqrt(complex);  // C++ linkage by default
extern "C" {
    double sqrt(double); // C linkage
}
```

Linkage specifications nest. A linkage specification does not establish a scope. A linkage-specification may only occur in file scope (§3.2). A linkage-specification for a class applies to non-member functions first declared within it. A linkage-specification for a function also applies to functions first declared within it. A linkage declaration with a string that is unknown to the implementation is an error.

If a function has more than one *linkage-specification*, they must agree; that is, they must specify the same *string*. A function declaration without a linkage specification may not precede the first linkage specification for that function. A function may be declared without a linkage specification after an explicit linkage specification has been seen; the linkage explicitly specified in the earlier declaration is not affected by such a function declaration.

At most one of a set of overloaded functions (§13) with a particular name can have C linkage.

Linkage can be specified for objects. For example,

```
extern "C" {
    // ...
    _iobuf _iob[_NFILE];
    // ...
    int _flsbuf(unsigned,_iobuf*);
    // ...
}
```

Functions and objects may be declared static within the {} of a linkage specification. In that case, the linkage directive is ignored for that function or object. Otherwise, a function declared in a linkage specification behaves as if it was explicitly declared extern. For example,

```
extern "C" double f();
static double f(); // error
is an error (§7.1.1).
```

Linkage from C++ to objects defined in other languages and to objects defined in C++ from other languages is implementation and language dependent. Only where the object layout strategies of two language implementations are sufficiently similar can such linkage be achieved.

Where the name of a programming language is used to name a style of linkage in the string in a linkage-specification, it is recommended that the spelling be taken from the document defining that language, for example, Ada (not ADA) and FORTRAN (not Fortran).

## 8. Declarators

The declarator-list appearing in a declaration is a comma-separated sequence of declarators, each of which may have an initializer.

```
declarator-list:
    init-declarator
    declarator-list , init-declarator
init-declarator:
    declarator initializeropt
```

The two components of a declaration are the specifiers (decl-specifiers; §7.1) and the declarators (declarator-list). The specifiers indicate the fundamental type, storage class, etc., of the objects and functions being declared. The declarators specify the names of these objects and functions and (optionally) modify the type with operators such as \* (pointer to) and () (function returning). Initial values can also be specified in a declarator; initializers are discussed in §8.4 and §12.6.

Declarators have the syntax:

```
declarator:
        dname
        ptr-operator declarator
        declarator ( argument-declaration-list ) co-qualifier-listopt
        declarator [ constant-expressionout ]
         ( declarator )
ptr-operator:
         * cv-qualifier-listopt
         & cv-qualifier-listopt
        class-name :: * co-qualifier-listopt
co-qualifier-list:
        co-qualifier co-qualifier-listopt
co-qualifier:
        const
        volatile
dname:
        name
        class-name
         ~ class-name
        typedef-name
```

A class-name has special meaning in a declaration of the class of that name and when qualified by that name using the scope resolution operator :: (§12.1, §12.4).

# 8.1 Type Names

To specify type conversions explicitly, and as an argument of sizeof or new, the name of a type must be specified. This is accomplished with a type-name, which is syntactically a declaration for an object or function of that type that omits the name of the object or function.

```
type-name:
type-specifier abstract-declaratorout
```

abstract-declarator:

```
ptr-operator abstract-declaratoropt
abstract-declaratoropt ( argument-declaration-list ) co-qualifier-listopt
abstract-declaratoropt [ constant-expressionopt ]
( abstract-declarator )
```

It is possible to identify uniquely the location in the abstract-declarator where the identifier would appear if the construction were a declarator in a declaration. The named type is then the same as the type of the hypothetical identifier. For example,

```
int
                              // int i
int * // int *pi
int *[3] // int *p[3]
int (*)[3] // int (*p3i)[3]
int *() // int *f()
int (*)(double) // int (*pf)(double)
```

name respectively the types "integer," "pointer to integer," "array of 3 pointers to integers," "pointer to array of 3 integers," "function taking no arguments and returning pointer to integer," and "pointer to function taking a double argument and returning an integer."

# 8.2 Meaning of Declarators

A list of declarators appears after a (possibly empty) list of decl-specifiers (§7.1). Each declarator contains exactly one *dname*; it specifies the identifier that is declared. Except for the declarations of some special functions (§12.3, §13.4) a dname will be a simple identifier. An auto, static, extern, register, friend, inline, virtual, or typedef specifier applies directly to each dname in a declarator-list; the type of each dname depends on both the declspecifiers (§7.1) and its declarator.

Thus, a declaration of a particular identifier has the form

where T is a type and D is a declarator. In a declaration where D is an unadorned identifier the type of this identifier is T.

In a declaration where D has the form

```
(D1)
```

the type of D1 is the same as that of D. Parentheses do not alter the type of the embedded dname, but they may alter the binding of complex declarators.

#### 8.2.1 Pointers

In a declaration T D where D has the form

```
* cv-qualifier-listopt D1
```

the type of the contained identifier is "... co-qualifier-list pointer to T." The co-qualifiers apply to the pointer and not to the object pointed to.

For example, the declarations

```
const ci = 10, *pc = &ci, *const cpc = pc;
int i, *p, *const cp = &i;
```

declare ci, a constant integer; pc, a pointer to a constant integer; cpc, a constant pointer to a constant integer; i, an integer; p, a pointer to integer; and cp, a constant pointer to integer. The value of ci, cpc, and cp cannot be changed after initialization. The value of pc can be changed, and so can the object pointed to by cp. Examples of legal operations are:

```
i = ci; *cp = ci; pc++; pc = cpc; pc = p; // ok
```

Examples of illegal operations are:

```
ci = 1; ci++; *pc = 2; cp = &ci; cpc++; p = pc; // errors
```

Each is illegal because it would either change the value of an object declared const or allow it to be changed through an unqualified pointer later.

volatile specifiers are handled similarly.

See also §5.17 and §8.4.

There can be no pointers to references (§8.2.2) or pointers to bit-fields (§9.6).

#### 8.2.2 References

In a declaration T D where D has the form

```
& co-qualifier-listopt D1
```

the type of the contained identifier is "... cv-qualifier-list reference to T." The type void& is not permitted.

For example,

```
void f(double& a) { a += 3.14; }
// ...
double d = 0;
f(d);
```

declares a to be a reference argument of f so that the call f(d) will add 3.14 to d.

```
int v[20];
// ...
int& g(int i) { return v[i]; }
// ...
g(3) = 7;
```

declares the function g() to return a reference to an integer so that g(3) = 7 will assign 7 to the fourth element of the array v.

```
void h(link*& p)
{
          p->next = first;
          first = p;
          p = 0;
}
// ...
link* q = new link;
h(q);
```

declares p to be a reference to a pointer to link so that h(q) will leave q with the value 0. See also §8.4.3.

There can be no references to references, no references to bit-fields (§9.6), no arrays of references, and no pointers to references. The declaration of a reference must contain an *initializer* (§8.4.3) except when the declaration contains an explicit extern specifier (§7.1.1), or is a class member (§9.2) declaration within a class declaration, the declaration of an argument type, or the declaration of a return type (§8.2.5).

#### 8.2.3 Pointers to Members

In a declaration T D where D has the form

```
class-name :: * co-qualifier-listopt D1
```

the type of the contained identifier is "... co-qualifier-list pointer to member of class class-name of type T."

For example,

```
class X {
public:
      void f(int);
      int a:
};
int X::* pmi = &X::a;
void (X::* pmf) (int) = &X::f;
```

declares pmi and pmf to be a pointer to a member of X of type int and a pointer to a member of X of type void (int), respectively. They can be used like this:

```
X obj;
11 ...
obj.*pmi = 7;
                  // assign 7 to an integer
                  // member of obj
(obj.*pmf)(7);
                 // call a function member of obj
                  // with the argument 7
```

Note that a pointer to member cannot point to a static member of a class (§9.4). See also §5.5 and §5.3.

### 8.2.4 Arrays

In a declaration T D where D has the form

```
D1 [constant-expression<sub>opt</sub>]
```

then the contained identifier has type "... array of T." If the constant-expression (§5.19) is present, it must be of integral type and have a value greater than 0. The constant expression specifies the number of elements in the array. If the constant expression is N, the array has N elements numbered 0 to N-1.

An array may be constructed from one of the fundamental types (except void), from a pointer, from a pointer to member, from a class, from an enumeration, or from another array.

When several "array of" specifications are adjacent, a multi-dimensional array is created; the constant expressions that specify the bounds of the arrays may be missing only for the first member of the sequence. This elision is useful for function arguments of array types and when the array is external and the actual definition, which allocates storage, is given elsewhere. The first constant-expression may also be omitted when the declarator is followed by an initializer-list (§8.4). In this case the size is calculated from the number of initial elements supplied (§8.4.1).

The declaration

```
float fa[17], *afp[17];
```

declares an array of float numbers and an array of pointers to float numbers. The declaration

```
static int x3d[3][5][7];
```

declares a static three-dimensional array of integers, with rank  $3\times5\times7$ . In complete detail, x3d is an array of three items; each item is an array of five arrays; each of the latter arrays is an array of seven integers. Any of the expressions x3d, x3d[i], x3d[i][j], x3d[i][j][k] may reasonably appear in an expression.

When an identifier of array type appears in an expression, except as the operand of sizeof or & or used to initialize a reference (&8.4.3), it is converted into a pointer to the first member of the array. Because of this conversion, arrays are not modifiable lvalues. Except where it has been declared for a class (&13.4.5), the subscript operator [] is interpreted in such a way that E1[E2] is identical to \*((E1)+(E2)). Because of the conversion rules that apply to +, if E1 is an array and E2 an integer, then E1[E2] refers to the E2-th member of E1. Therefore, despite its asymmetric appearance, subscripting is a commutative operation.

A consistent rule is followed in the case of multi-dimensional arrays. If E is an n-dimensional array of rank  $i \times j \times \cdots \times k$ , then E appearing in an expression is converted to a pointer to an (n-1)-dimensional array with rank  $j \times \cdots \times k$ . If the  $\star$  operator, either explicitly or implicitly as a result of subscripting, is applied to this pointer, the result is the pointed-to (n-1)-dimensional array, which itself is immediately converted into a pointer.

For example, consider

```
int x[3][5];
```

Here x is a  $3\times5$  array of integers. When x appears in an expression, it is converted to a pointer to (the first of three) 5-membered arrays of integers. In the expression x[i], which is equivalent to \*(x+i), x is first converted to a pointer as described; then x+i is converted to the type of x, which involves multiplying i by the length of the object to which the pointer points, namely 5 integer objects. The results are added and indirection applied to yield an array (of 5 integers), which in turn is converted to a pointer to the first of the integers. If there is another subscript the same argument applies again; this time the result is an integer.

It follows from all this that arrays in C++ are stored row-wise (last subscript varies fastest) and that the first subscript in the declaration helps determine the amount of storage consumed by an array but plays no other part in subscript calculations.

#### 8.2.5 Functions

In a declaration T D where D has the form

```
D1 ( argument-declaration-list ) co-qualifier-listopt
```

the contained identifier has the type "... co-qualifier-listopt function taking arguments of type argument-declaration-list and returning T."

```
argument-declaration-list:
    arg-declaration-list<sub>opt</sub> ... opt
    arg-declaration-list , ...

arg-declaration-list:
    argument-declaration
    arg-declaration-list , argument-declaration

argument-declaration:
    decl-specifiers declarator
    decl-specifiers declarator = expression
    decl-specifiers abstract-declarator<sub>opt</sub>
    decl-specifiers abstract-declarator<sub>opt</sub> = expression
```

If the argument-declaration-list terminates with an ellipsis, the number of arguments is known only to be equal to or greater than the number of argument types specified; if it is empty, the function takes no arguments. The argument list (void) is equivalent to the empty argument list. Except for this special case void may not be an argument type (though types derived from void, such as void\*, may). Where legal, ", ..." is synonymous with "...". The standard header <stdarg.h> contains a mechanism for accessing arguments passed using the ellipsis.

A single name may be used for several different functions in a single scope; this is function overloading (§13.1). All declarations for a function taking a given set of arguments must agree exactly both in the type of the value returned and in the number and type of arguments; the presence or absence of the ellipsis is considered part of the function type. Argument types that differ only in the use of typedef names or unspecified argument array bounds agree exactly. The argument types, but not the default arguments (§8.2.6), are part of the function type. A co-qualifier-list can be part of a member function declaration, member function definition, or pointer to member function only; see §9.3.1. It is part of the function type.

Functions cannot return arrays or functions, although they can return pointers and references to such things. There are no arrays of functions, although there may be arrays of pointers to functions.

The argument-declaration-list is used to check and convert actual arguments in calls and to check pointer-to-function assignments and initializations.

An identifier can optionally be provided as an argument name; if present in a function declaration, it cannot be used since it immediately goes out of scope; if present in a function definition (§8.3), it names a formal argument. In particular, argument names are also optional in function definitions and names used for an argument in different declarations and the definition of a function need not be the same.

#### The declaration

```
int i, *pi, f(), *fpi(int), (*pif)(const char*, const char*);
```

declares an integer i, a pointer pi to an integer, a function f taking no arguments and returning an integer, a function fpi taking an integer argument and returning a pointer to an integer, and a pointer pif to a function which takes two pointers to constant characters and returns an integer. It is especially useful to compare the last two. The binding of \*fpi(int) is \* (fpi (int)), so that the declaration suggests, and the same construction in an expression requires, the calling of a function fpi, and then using indirection through the (pointer) result to yield an integer. In the declarator (\*pif) (const char\*, const char\*), the extra parentheses are necessary to indicate that indirection through a pointer to a function yields a function, which is then called.

#### The declaration

```
fseek(FILE*, long, int);
```

declares a function taking three arguments of the specified types. Since no return value type is specified it is taken to be int (§7.1.6). The declaration

```
printf(const char* ...);
```

declares a function that can be called with varying number and types of arguments. For example:

```
printf("hello world");
printf("a=%d b=%d", a, b);
```

However, it must always have a value that can be converted to a const char\* as its first argument.

### 8.2.6 Default Arguments

If an expression is specified in an argument declaration this expression is used as a default argument. All subsequent arguments must have default arguments. Default arguments will be used in calls where trailing arguments are missing. A default argument cannot be redefined by a later declaration (not even to the same value). However, a declaration may add default arguments not given in previous declarations.

The declaration

```
point(int = 3, int = 4);
```

declares a function that can be called with zero, one, or two arguments of type int. It may be called in any of these ways:

```
point(1,2); point(1); point();
```

The last two calls are equivalent to point (1, 4) and point (3, 4), respectively.

Default argument expressions have their names bound and their types checked at the point of declaration, and are evaluated at each point of call. In the following example, g will be called with the value f(2):

```
int a = 1;
int f(int);
int g(int x = f(a)); // default argument: f(::a)

void h() {
    a = 2;
    {
        int a = 3;
        g(); // g(f(::a))
    }
}
```

Note that default arguments are evaluated before entry into a function and that the order of evaluation of function arguments is implementation dependent. Consequently, formal arguments of a function may not be used in default argument expressions. Formal arguments of a function declared before a default argument expression are in scope and may hide global and class member names. For example:

Similarly, the declaration of X:=mem1 () in the following example is illegal because no object is supplied for the non-static member X:=a used as an initializer:

However, the declaration of X::mem2() is legal, since no object is needed to access the static member X::b. Classes, objects, and members are described in §9.

A default argument is not part of the type of a function:

### 8.3 Function Definitions

Function definitions have the form

```
fct-definition:

decl-specifiers<sub>opt</sub> declarator ctor-initializer<sub>opt</sub> fct-body

fct-body:

compound-statement
```

The declarator in a fct-definition must contain a declarator with the form

```
D1 ( argument-declaration-list ) cv-qualifier-list<sub>opt</sub> as described in §8.2.5.
```

The formal arguments are in the scope of the outermost block of the fct-body.

A simple example of a complete function definition is

```
int max(int a, int b, int c)
{
    int m = (a > b) ? a : b;
    return (m > c) ? m : c;
}
```

Here int is the decl-specifiers; max(int a, int b, int c) is the declarator; { ... } is the fct-body.

A ctor-initializer is used only in a constructor; see §12.1 and §12.6.

A cv-qualifier-list can be part of a member function declaration, member function definition, or pointer to member function only; see §9.3.1. It is part of the function type.

Note that unused formal arguments need not be named. For example:

```
void print(int a, int)
{
    printf("a = %d\n",a);
}
```

# 8.4 Initializers

A declarator may specify an initial value for the identifier being declared.

Automatic, register, static, and external variables may be initialized by arbitrary expressions involving constants and previously declared variables and functions.

```
int f(int);
int a = 2;
int b = f(a);
```

A pointer of type const T\*, that is, a pointer to constant T, can be initialized with a pointer of type T\*, but the reverse initialization is illegal. Objects of type T can be initialized with objects of type T independently of const and volatile modifiers on both the initialized variable and on the initializer. For example:

The reason for the two errors is the same: had those initializations been allowed they would have allowed the value of something declared const to be changed through an unqualified pointer.

Default argument expressions are more restricted; see §8.2.6.

Variables with storage class static (§3.5) that are not initialized are guaranteed to start off as 0 converted to the appropriate type. The initial values of automatic and register variables that are not initialized are undefined.

When an initializer applies to a pointer or an object of arithmetic type, it consists of a single expression, perhaps in braces. The initial value of the object is taken from the expression; the same conversions as for assignment are performed.

Note that since () is not an initializer,

```
X a();
```

is not the declaration of an object of class X, but the declaration of a function taking no argument and returning an X.

Initialization of objects of classes with constructors is described in §12.6.1. Copying of class objects is described in §12.8.

The order of initialization of static objects is described in §3.4 and §6.3.

### 8.4.1 Aggregates

An aggregate is an array or an object of a class (§9) with no constructors (§12.1), no private or protected members (§11), no base classes (§10), and no virtual functions (§10.2). When an aggregate is initialized the initializer may be an initializer-list consisting of a brace-enclosed, comma-separated list of initializers for the members of the aggregate, written in increasing subscript or member order. If the aggregate contains subaggregates, this rule applies recursively to the members of the subaggregate. If there are fewer initializers in the list than there are members of the aggregate, then the aggregate is padded with 0's.

For example,

```
struct S { int a; char* b; int c; };
S ss = \{ 1, "asdf" \};
```

initializes ss.a with 1, ss.b with "asdf", and ss.c with 0.

An aggregate that is a class may also be initialized with an object of its class or of a class publicly derived from it (§12.8).

Braces may be elided as follows. If the initializer-list begins with a left brace, then the succeeding comma-separated list of initializers initializes the members of the aggregate; it is erroneous for there to be more initializers than members. If, however, the initializer-list or a sub-aggregate does not begin with a left brace, then only enough elements from the list are taken to account for the members of the aggregate; any remaining members are left to initialize the next member of the aggregate of which the current aggregate is a part.

For example,

```
int x[] = \{ 1, 3, 5 \};
```

declares and initializes x as a one-dimensional array that has three members, since no size was specified and there are three initializers.

```
float y[4][3] = {
      { 1, 3, 5 },
      { 2, 4, 6 },
      { 3, 5, 7 },
};
```

is a completely-bracketed initialization: 1, 3, and 5 initialize the first row of the array y[0], namely y[0][0], y[0][1], and y[0][2]. Likewise the next two lines initialize y[1] and y[2]. The initializer ends early and therefore y[3] is initialized with 0's. Precisely the same effect could have been achieved by

```
float y[4][3] = {
      1, 3, 5, 2, 4, 6, 3, 5, 7
};
```

The last (rightmost) index varies fastest (§8.2.4).

The initializer for y begins with a left brace, but that for y[0] does not, therefore three elements from the list are used. Likewise the next three are taken successively for y[1] and y[2]. Also,

```
float y[4][3] = {
     {1}, {2}, {3}, {4}
};
```

initializes the first column of y (regarded as a two-dimensional array) and leaves the rest 0. Initialization of arrays of objects of a class with constructors is described in §12.6.1.

The initializer for a union with no constructor is either a single expression of the same type, or a brace-enclosed initializer for the first member of the union. For example,

```
union u { int a; char* b; };
u a = { 1 };
ub = a;
                    // error
uc=1;
u d = { 0, "asdf" }; // error
                    // error
u e = { "asdf" };
```

There may not be more initializers than there are members or elements to initialize. For example,

```
char cv[4] = { 'a', 's', 'd', 'f', 0 }; // error
is an error.
```

## 8.4.2 Character Arrays

A char array (whether signed or unsigned) may be initialized by a string; successive characters of the string initialize the members of the array. For example,

```
char msg[] = "Syntax error on line %s\n";
```

shows a character array whose members are initialized with a string. Note that because '\n' is a single character and because a trailing '\0' is appended, sizeof (msg) is 25.

There may not be more initializers than there are array elements. For example,

```
char cv[4] = "asdf"; // error
```

is an error since there is no space for the implied trailing '\0'.

#### 8.4.3 References

A variable declared to be a T&, that is "reference to type T" (§8.2.2), must be initialized by an object of type T or by an object that can be converted into a T. For example:

```
int& r = i; // `r' refers to `i'
r = 1; // the value of 'i' becomes 1
int* p = &r; // 'p' points to 'i'
int& rr = r; // 'rr' refers to what 'r' refers to, that is to 'i'
```

A reference cannot be changed to refer to another object after initialization. Note that initialization of a reference is treated very differently from assignment to it. Argument passing (§5.2.2) and function value return (§6.6.3) are initializations.

The initializer may be left out for a reference only in an argument declaration (§8.2.5), in the declaration of a function return type, in the declaration of a class member within its class declaration (§9.2), and where the extern specifier is explicitly used. For example:

```
// error: initializer missing
extern int& r2; // ok
```

If the initializer for a reference to type T is an Ivalue of type T or of a type publicly derived (§10) from T the reference will refer to the initializer; otherwise, an object of type T will be created and initialized with the initializer. The reference then becomes a name for that object. The lifetime of an object created in this way is the scope in which it is created (§3.5). For example:

```
double& rd = 1;
```

is legal and rd will point to a double containing the value 1.0. Also,

```
char c = 'c';
char& rc = c;
signed char& rsc = c;
unsigned char& ruc = c;
```

Here, either rsc or ruc (but not both) will be initialized to a temporary dependent on whether 'plain' char is signed or unsigned. The initialization of rc does not require the use of a temporary.

Note that a reference to a class B can be initialized by an object of a class D provided B is a public base class of D (in that case a D is a B); see §4.7.

## 9. Classes

A class is a type. Its name becomes a class-name (§9.1), that is, a reserved word within its scope:

```
class-name:
identifier
```

Class-specifiers and elaborated-type-specifiers are used to make class-names. An object of a class consists of a (possibly empty) sequence of members:

The name of a class can be used as a class-name even within the member-list of the class specifier itself. A class-specifier is commonly referred to as a class declaration. A class is considered defined when its class-specifier has been seen even though its member functions are in general not yet defined.

Class objects may be assigned, passed as arguments to functions, and returned by functions (except objects of classes for which copying has been restricted; see §12.8). Other plausible operators, such as equality comparison, can be defined by the user; see §13.4.

A structure is a class declared with the class-key struct; its members and base classes (§10) are public by default (§11). A union is a class declared with the class-key union; its members are public by default and it holds only one member at a time (§9.5).

## 9.1 Class Names

A class declaration introduces a new type. For example:

```
struct X { int a; };
struct Y { int a; };
X a1;
Y a2;
int a3;
```

declares three variables of three different types. This implies that

```
a1 = a2;  // error: Y assigned to X
a1 = a3;  // error: int assigned to X
```

are type mismatches, and that

```
int f(X);
int f(Y);
```

declare an overloaded (§13) function f() and not simply a single function f() twice. For the same reason,

```
struct S { int a; };
struct S { int a; }; // error, double definition
```

is an error because it defines S twice.

A class declaration introduces the class name into the scope where it is declared and hides any class, object, function, etc., of that name in an enclosing scope (§3.2). If a class name is declared in a scope where an object, function, or enumerator of the same name is also declared the class can only be referred to using an elaborated-type-specifier (§7.1.6). For example,

This re-use of a class name is not legal for classes with constructors (§12.1). An elaborated-type-specifier with a class-key used without declaring an object or function introduces a class name exactly like a class declaration but without declaring a class. For example,

```
struct s { int a; };

void g()
{
    struct s; // hide global struct 's'
    s* p; // refer to local struct 's'
    struct s { char* p; }; // declare local struct 's'
}
```

Such declarations allow declaration of classes that refer to each other. For example:

Declaration of friends is described in §11.4, operator functions in §13.4. If a class mentioned as a friend has not been declared its name is entered in the same scope as the name of the class containing the friend declaration (§11.4).

An elaborated-type-specifier (§7.1.6) can also be used in the declarations of objects and functions. It differs from a class declaration in that if a class of the elaborated name is in scope the elaborated name will refer to it. For example:

```
struct s { int a; };

void g()
{
    struct s* p; // refer to global `s'
    p->a = 1;
}
```

A name declaration takes effect immediately after the identifier is seen. For example,

```
class A * A;
```

first specifies A to be the name of a class and then redefines it as the name of a pointer to an object of that class. This means that the elaborated form class A must be used to refer to the class. Such artistry with names can be confusing and is best avoided.

A typedef-name (§7.1.3) that names a class is a class-name.

### 9.2 Class Members

```
member-list:
    member-declaration member-listopt
    access-specifier: member-listopt

member-declaration:
    decl-specifiersopt member-declarator-listopt;
    function-definition; opt
    qualified-name;

member-declarator-list:
    member-declarator
    member-declarator

member-declarator:
    declarator pure-specifieropt
    identifieropt: constant-expression

pure-specifier:
    = 0
```

A member-list may declare data, function, class, enum (§7.2), bit-field members (§9.6), friends (§11.4), and type names (§7.1.3, §9.1). A member-list may also contain declarations adjusting the access to member names; see §11.3. A member may not be declared twice in the member-list. The member-list defines the full set of members of the class. No member can be added elsewhere.

Note that a single name can denote several function members provided their types are sufficiently different (§13) and that a member-declarator cannot contain an initializer (§8.4).

A member may not be auto, extern, or register.

The decl-specifiers can be omitted in function declarations only. The member-declarator-list can be omitted after a class-specifier, an enum-specifier, or decl-specifiers of the form friend elaborated-type-specifier only. A pure-specifier may be used in the declaration of a virtual function only (§10.2).

Members that are class objects must be objects of previously declared classes. In particular, a class cl may not contain an object of class cl, but it may contain a pointer or reference to an object of class cl.

A simple example of a class declaration is:

```
struct tnode {
      char tword[20];
      int count;
      tnode *left;
      tnode *right;
};
```

which contains an array of 20 characters, an integer, and two pointers to similar structures. Once this declaration has been given, the declaration

```
tnode s, *sp;
```

declares s to be a tnode and sp to be a pointer to a tnode. With these declarations,

```
sp->count
```

refers to the count field of the structure to which sp points;

```
s.left.
```

refers to the left subtree pointer of the structure s; and

```
s.right->tword[0]
```

refers to the initial character of the tword member of the right subtree of s.

Data members of a class within the same access-specifier are allocated so that later members have higher addresses within a class object. The order of allocation across access-specifiers is implementation dependent. Implementation alignment requirements may cause two adjacent members not to be allocated immediately after each other; so may requirements for space for managing virtual functions (§10.2) and virtual base classes (§10.1); see also §5.4.

#### 9.3 Member Functions

A function declared as a member (without the friend specifier; §11.4) is called a member function, and is called using the class member syntax (§5.2.4). For example,

```
struct tnode {
     char tword[20];
      int count;
     tnode *left;
     tnode *right;
     void set(char*, tnode* 1, tnode* r);
```

Here set is a member function and can be called like this:

```
void f()
      tnode n1, n2;
      n1.set("abc", &n2, 0);
      n2.set("def",0,0);
```

The definition of a member function is considered to be within the scope of its class. This means that it (provided it is non-static §9.4) can use names of members of its class directly. If the definition of a member function is lexically outside the class declaration, the member function name must be qualified by the class name using the :: operator. For example:

The notation tnode::set specifies that the function set is a member of and in the scope of class tnode. The member names tword, count, left, and right refer to members of the object for which the function was called. Thus, in the call n1.set("abc", &n2,0), tword refers to n1.tword, and in the call n2.set("def",0,0) it refers to n2.tword. The functions strlen, error, and stropy must be declared elsewhere.

Members may only be defined (§3.1) outside their class declaration (provided they have already been declared in the class declaration); they may not be redeclared.

The effect of calling a non-static member function (§9.4) of a class X for something that is not an object of class X is undefined.

#### 9.3.1 The this Pointer

In a non-static (§9.3) member function, the keyword this is a pointer to the object for which the function is called. The type of this in a member function of a class X is X \*const unless the member function is declared const or volatile; in those cases, the type of this is const X \*const and volatile X \*const, respectively. See also §B.3.3. For example,

```
struct s {
    int a;
    int f() const;
    int g() { return a++; }
    int h() const { return a++; } // error
};
int s::f() const { return a; }
```

The a++ in the body of s::h is an error because it tries to modify (a part of) the object for which s::h() is called. This is not allowed in a const member function where this is a pointer to const, that is, \*this is a const.

A const member function (that is, a member function declared with the const qualifier) may be called for const and non-const objects, whereas a non-const member function may be called for a non-const object only. For example,

The call y.g() is an error because y is const and s::g() is a non-const member function that could (and does) modify the object for which it was called.

Similarly, only volatile member functions (that is, a member function declared with the volatile specifier) may be invoked for volatile objects. A member function can be both const and volatile.

Constructors (§12.1) and destructors (§12.4) need not be const member functions to be used for const objects.

#### 9.3.2 Inline Member Functions

A member function may be defined (§8.3) in the class declaration, in which case it is inline (§7.1.2). Defining a function within a class declaration is equivalent to declaring it inline and defining it immediately after the class declaration; this rewriting is considered to be done after preprocessing but before syntax analysis and type checking. Thus:

```
struct x {
             char* f() { return b; }
             char* b;
      1:
is equivalent to:
      int b;
      struct x {
            char* f();
             char* b;
      1:
      inline char* x::f() { return b; } // moved
```

Thus the b used in x::f() is X::b and not the global b.

Member functions can be defined even in local or nested class declarations where this rewriting would be syntactically illegal. In these cases the function definition is handled as if it occurred outside any function or class. It is still considered within the scope of its class, however. For example:

```
void f()
{
      int b;
      struct x {
            int mem;
            int f() { return mem; } // ok
            int g() { return b; } // error
      1:
      // ...
```

The b used in x::g() is undefined because, appearances to the contrary, x::g() is not in the scope of :: f() (§3.2).

The following rule limits the context sensitivity of the rewrite rules for inline functions, typedefs and nested classes (§9.7), and for class member declarations in general. A class-name or a typedef-name may not be redefined in a class declaration after being used in the class declaration, nor may a name that is not a class-name or a typedef-name be redefined to a classname or a typedef-name in a class declaration after being used in the class declaration. For example:

### 9.4 Static Members

A data or function member of a class may be declared static in the class declaration. There is only one copy of a static data member, shared by all objects of the class in a program. A static member is not part of objects of a class. Static members, except inline functions, of a global class have external linkage (§3.3). The declaration of a static member in its class declaration is *not* a definition. A definition is required elsewhere; see also §B.3.

A static member function does not have a this pointer so it can only access non-static members of its class by using . or ->. A static member function cannot be virtual. There cannot be a static and a non-static member function with the same name and the same argument types.

Static members of a class declared local to some function have no linkage and cannot be initialized. It follows that a local class cannot have static members that require initialization (except for the default "all zeros" initialization (§8.4)).

A static member mem of class cl can be referred to as cl::mem (§5.1), that is, independently of any object. It can also be referred to using the . and -> member access operators (§5.2.4); in this case, the expression on the left hand side of . or -> is not evaluated. It exists even if no objects of class cl have been created. For example,

```
class process {
    static int no_of_processes;
    static process* run_chain;
    static process* running;
    static process* idle;
    // ...
public:
    // ...
    int state();
    static void reschedule();
    // ...
};
f() {
    process::reschedule();
}
```

Static members of a global class are initialized exactly like global objects and only in file scope. For example,

```
void process::reschedule() { /* ... */ };
int process::no_of_processes = 1;
process* process::running = get_main();
process* process::run_chain = process::running;
```

Static members obey the usual class member access rules (§11) except that they can be initialized (in file scope).

The type of a static member does not involve its class name; thus the type of process::no\_of\_processes is int and the type of &process::reschedule is void(\*)().

#### 9.5 Unions

A union may be thought of as a structure whose member objects all begin at offset 0 and whose size is sufficient to contain any of its member objects. At most one of the member objects can be stored in a union at any time. A union may have member functions (including constructors and destructors). A union may not have base classes. A union may not be used as a base class. An object of a class with a constructor or a destructor cannot be a member of a union. A union can have no static data members.

A union of the form

```
union { member-list } ;
```

is called an anonymous union; it defines an unnamed object (and not a type). The names of the members of an anonymous union must be distinct from other names in the scope in which the union is declared; they are used directly in that scope without the usual member access syntax (§5.2.4). For example,

```
void f()
{
      union { int a; char* p; };
      a = 1;
      // ...
      p = "asdf";
      // ...
```

Here a and p are used like ordinary (non-member) variables, but since they are union members they have the same address.

A global anonymous union must be declared static. An anonymous union may not have private or protected members (§11).

A union may not have function members.

A union for which objects or pointers are declared is not an anonymous union. For example,

```
union { int aa; char* p; } obj, *ptr = &obj;
aa = 1; // error
ptr->aa = 1; // ok
```

The assignment to "plain" aa is illegal since the member name is not associated with any particular object.

#### 9.6 Bit-Fields

A member-declarator of the form

```
identifieropt: constant-expression
```

specifies a bit-field; its length is set off from the bit-field name by a colon. Allocation of bitfields within a class object is implementation dependent. Fields are packed into some addressable allocation unit. Fields straddle allocation units on some machines and not on others. Alignment of bit-fields is implementation dependent. Fields are assigned right-to-left on some machines, left-to-right on others.

An unnamed bit-field is useful for padding to conform to externally-imposed layouts. As a special case, an unnamed bit-field with a width of 0 specifies alignment of the next bit-field at an allocation unit boundary.

A bit-field must have integral type (§3.6.1). It is implementation dependent whether a "plain" int field is signed or unsigned. The address-of operator & may not be applied to a bit-field,

so there are no pointers to bit-fields. There are no references to bit-fields either.

### 9.7 Nested Class Declarations

A class may be declared within another class. That, however, is only a notational convenience since the inner class has the same scope as the enclosing class. For example:

```
int x;

class enclose {
    int x;
    class inner {
        int y;
        void f(int);
    };
    int g(inner*);
};

inner a;

void inner::f(int i) { x = i; } // assign to ::x
int enclose::g(inner* p) { return p->y; } // error
```

The definition of enclose::g() is an error since inner::y is private and enclose::g() has no special access rights to it despite class inner being declared within class enclose.

Similarly, typedefs (§7.1.3) and enumeration names (§7.2) declared within a class can be used outside. For example,

```
class X {
     typedef int I;
     I a;
};
```

The "exporting" of classes and typedefs and enumeration names into an enclosing scope continues until the global or a local (block) scope is reached.

### 10. Derived Classes

A list of base classes may be specified in a class declaration using the notation:

```
base-spec:
         : base-list
base-list:
        base-specifier
        base-list , base-specifier
base-specifier:
        class-name
        virtual access-specifieropt class-name
        access-specifier virtualopt class-name
access-specifier:
        private
        protected
        public
```

The class-name in a base-specifier must denote a previously declared class (§9), which is called a base class for the class being declared. A class is said to be derived from its base classes. For the meaning of access-specifier see §11. protected may not be used as the access-specifier in a base-specifier for a base class. Unless re-defined in the derived class, members of a base class can be referred to as if they were members of the derived class. The base class members are said to be inherited by the derived class. A base member can also be referred to explicitly using the :: operator (§5.1). This allows a name that has been re-defined in the derived class to be accessed. A derived class can itself serve as a base class subject to access control; see §11.2. A pointer to a derived class may be implicitly converted to a pointer to a public base class (§4.6). A reference to a derived class may be implicitly converted to a reference to a public base class (§4.6).

For example:

```
class base {
public:
      int a, b;
class derived : public base {
public:
      int b, c;
1;
void f()
      derived d;
      d.a = 1;
      d.base::b = 2;
      d.b = 3;
      d.c = 4;
      base* bp = &d; // standard conversion: derived* to base*
```

assigns to the four members of d and makes bp a pointer to d.

A class is called a direct base if it is mentioned in the base-list, and an indirect base if it is not but is a base class of one of the classes mentioned in the base-list.

Note that in the class-name: name notation, name may be a name of a member of an indirect base class; the notation simply specifies a class in which to start looking for name. For example:

```
class A { public: int f(); };
class B : A { };
class C : B { public: int f(); };
int C::f()
{
     B::f(); // call A's f()
}
```

Here, A::f() is called since it is the only f() in B.

## 10.1 Multiple Base Classes

A class may be derived from any number of base classes (i.e., multiple inheritance):

```
class A { ... };
class B { ... };
class C { ... };
class D : public A, public B, public C { ... };
```

The order of derivation is not significant except possibly for default initialization by constructor (§12.1), for cleanup (§12.4), and for storage layout (§5.4, §9.2, §11.1). The order in which storage is allocated for base classes is implementation dependent.

A class may not be specified as a direct base class of a derived class more than once but it may be an indirect base class more than once:

```
class B { ... };
class D : B, B { ... }; // illegal

class X : public B { ... };
class Y : public B { ... };
class Z : public X, public Y { ... }; // legal
```

In this case an object of class Z will have two sub-objects of class B. Note that every access to a member of B in a D would have been ambiguous (§10.1.1).

The keyword virtual may be added to a base class specifier. A single sub-object of the virtual base class is shared by every base class that specified the base class to be virtual. For example:

```
class X : virtual public B { ... };
class Y : virtual public B { ... };
class Z : public X, public Y { ... };
```

Here class z has only one sub-object of class B.

A class may have both virtual and non-virtual base classes of a given type:

```
class X : virtual public B { ... };
class Y : virtual public B { ... };
class Z : public B { ... };
class AA : public X, public Y, public Z { ... };
```

Here class AA has two sub-objects of class B: Z's B and the virtual B shared by X and Y.

#### 10.1.1 Ambiguities

Access to base class members must be unambiguous. Access to a base class member is ambiguous if the expression used refers to more than one function, object, or enumerator. The check for ambiguity takes place before access control (§11) and before type checking.

```
class A {
public:
    int a;
    int f();
1:
class B {
    int a;
public:
    int f;
class C : public A, public B {};
void g(C* pc)
    pc->a = 1; // error, ambiguous: A::a or B::a ?
    pc->f();
               // error, ambiguous: A::f or B::f ?
```

Ambiguities can be resolved by qualifying a name with its class name:

```
class A {
public:
    int f();
1:
class B {
public:
    int f();
};
class C : public A, public B {
    int f() { return A::f() + B::f(); }
};
```

When virtual base classes are used, a function, object, or enumerator may be reached through more than one path through the directed acyclic graph of base classes. This is not an ambiguity. The identical use with non-virtual base classes is an ambiguity; in that case more than one sub-object is involved. For example:

```
class V { public: int v; };
class A { public: int a; };
class B : public A, public virtual V {};
class C : public A, public virtual V {};
class D : public B, public C { public: void f(); };
void D::f()
{
      v++; // ok: only one 'v' in 'D'
     a++; // error, ambiguous: two 'a's in 'D'
```

When virtual base classes are used, more than one function, object, or enumerator may be reached through paths through the directed acyclic graph of base classes. For objects and enumerators this is an ambiguity. For functions it is not in all cases.

A function B::f() dominates a function A::f() if its class B has A as a base. If a function dominates another no ambiguity exists between the two and the dominant function is used where there is a choice. For example:

```
class A { public: int f(); int x; };
class B : public virtual A { public: int f(); int x; };
class C : public virtual A { };
class D : public B, public C { void g(); };
void D::g()
      x++; // error, ambiguous: A::x or B::x ?
      f(); // ok: B::f() dominates A::f()
```

An explicit or implicit conversion from a derived class to one of its base classes must unambiguously refer to the same object representing the base class. For example:

```
class V { };
class A { };
class B : public A, public virtual V { };
class C : public A, public virtual V { };
class D : public B, public C { };
void g()
      D d;
      B*pb = &d;
      A* pa = &d; // error, ambiguous: C's A or B's A?
      V* pv = &d; // fine: only one V sub-object
}
```

## 10.2 Virtual Functions

If a class base contains a virtual (§7.1.1) function vf, and a class derived derived from it also contains a function vf of the same type then a call of vf for an object of class derived invokes derived::vf (even if the access is through a pointer or reference to base). The derived class function is said to override the base class function. If the function types (§8.2.5) are different, however, the functions are considered different and the virtual mechanism is not invoked (see also §13.1). It is an error for a derived class function to differ from a virtual base class function in the return type only. For example:

```
struct base {
      virtual void vf1();
      virtual void vf2();
      virtual void vf3();
      void f();
};
```

```
class derived : public base {
public:
     void vfl();
     void vf2(int);
     char vf3();
                    // error: differs in return type only
     void f();
};
void g()
     derived d;
     base* bp = &d; // standard conversion: derived* to base*
                     // calls derived::vfl
     bp->vf1();
                     // calls base::vf2
     bp->vf2();
     bp->f();
                     // calls base::f
```

The calls invoke derived::vf1, base::vf2, and base::f, respectively, for the class derived object named d. That is, the interpretation of the call of a virtual function depends on the type of the object for which it is called, whereas the interpretation of a call of a nonvirtual member function depends only on the type of the pointer or reference denoting that object.

The virtual specifier implies membership, so a virtual function cannot be a global (nonmember) (§7.1.1) function. A virtual function cannot be a static member either since a virtual function call relies on a specific object for determining which function to invoke. A virtual function can be declared a friend in another class. An overriding function is itself considered virtual. The virtual specifier may be used for an overriding function in the derived class, but such use is redundant. A virtual function in a base class must be defined or declared pure (§10.3). A virtual function that has been defined in a base class need not be defined in a derived class. In that case, the function defined for the base class is used in all calls.

#### 10.3 Abstract Classes

An abstract class is a class that can only be used as a base class of some other class; no objects of an abstract class may be created except as sub-objects of some other class. A class is abstract if it has at least one pure virtual function. A virtual function is specified pure by using a pure-specifier (§9.2) in the function declaration in the class declaration. A pure virtual function need only be defined if explicitly called with the qualified-name syntax (§5.1). For example:

```
class shape {
                        // abstract class
      point center;
      // ...
public:
      where() { return center; }
      move(point p) { center=p; draw(); }
      virtual void rotate(int) = 0; // pure virtual function
      virtual void draw() = 0;
                                     // pure virtual function
      // ...
};
```

An abstract class may not be used as an argument type or as a function return type. Pointers and references to an abstract class may be declared. For example:

However, references that require the use of a temporary in the initialization (§8.4.3) are illegal.

A class with an abstract class A as its immediate base class must define or declare pure every pure virtual function in A.

```
class circle : public shape {
    int radius;
public:
    void rotate(int) {}
    void draw(); // circle::draw() must be defined somewhere
};
```

Member functions can be called from a constructor of an abstract class; calling a pure virtual function directly or indirectly from such a constructor causes a run-time error.

The abstract class mechanism supports the notion of a general concept, such as a shape, of which only more concrete variants, such as circle and square, can actually be used. An abstract class can also be used to define an interface for which derived classes provide a variety of implementations.

## 10.4 Summary of Scope Rules

The scope rules for C++ programs can now be summarized. These rules apply uniformly for all names (including *typedef-names* (§7.1.3) and *class-names* (§9.1)) wherever the grammar allows such names in the context discussed by a particular rule. This section discusses lexical scope only; see §3.3 for an explanation of linkage issues. The notion of point of declaration is discussed in (§3.2).

When looking for the object, function, type, etc., that a name refers to, at first the name only is considered and ambiguities are detected (§10.1.1). Only if the name is found to be unambiguous in its scope are access rules considered (§11). Only if no access control errors are found is the type of the object, function, etc., considered.

A name used outside any function and class or prefixed by the unary scope operator :: (and not qualified by the binary :: operator or the -> or . operators) must be the name of a global object, function, or enumerator.

A name specified after X::, after obj., where obj is an X or a reference to X, or after ptr->, where ptr is a pointer to X, must be the name of a member of class X or be a member of a base class of X.

A name that is not qualified in any of the ways described above and that is used in a function that is not a non-static class member must be declared in the block in which it occurs or in an enclosing block or be a global name. The declaration of a local name hides declarations of the same name in enclosing blocks and global names. In particular, no overloading occurs of names in different scopes (§13.4).

A name that is not qualified in any of the ways described above and that is used in a function that is a non-static member of class X must be declared in the block in which it occurs or in an enclosing block, be a member of class X or a base class of class X, or be a global name. The declaration of a local name hides declarations of the same name in enclosing blocks, members of the function's class, and global names. The declaration of a member name hides declarations of the same name in base classes.

A function argument name in a function definition (§8.3) is in the scope of the outermost block of the function. A function argument name in a function declaration (§8.2.5) that is not a function definition is in no scope at all. A default argument is in the scope determined by the point of declaration (§3.2) of its argument, but may not access local variables or non-static class members; it is evaluated at each point of call (§8.2.6).

A ctor-initializer (§12.6.2) is evaluated in the scope of the outermost block of the constructor it is specified for. In particular, it can refer to the constructor's argument names.

## 11. Member Access Control

A member of a class can be

private; that is, its name can be used only by member functions and friends of the class in which it is declared.

protected; that is, its name can be used only by member functions and friends of the class in which it is declared and by member functions and friends of classes derived from this class (see §11.5).

public; that is, its name can be used by any function.

Members of a class declared with the keyword class are private by default. Members of a class declared with the keyword struct are public by default. For example:

```
class X {
    int a; // X::a is private by default
};
struct S {
    int a; // S::a is public by default
};
```

All members of a union are public and no access-specifier (§11.1) is allowed in a union.

## 11.1 Access Specifiers

Member declarations may be labelled by an access-specifier (§10):

```
access-specifier: member-listopt
```

An access-specifier specifies the access rules for members following it until the end of the class or until another access-specifier is encountered. For example:

```
class X {
   int a; // X::a is private by default: 'class' used
public:
   int b; // X::b is public
   int c; // X::c is public
};
```

Any number of access specifiers is allowed and no particular order is required. For example:

```
struct S {
   int a; // S::a is public by default: 'struct' used
protected:
   int b; // S::b is protected
private:
   int c; // S::c is private
public:
   int d; // S::d is public
};
```

The order of allocation of data members with separate access-specifiers is implementation dependent (§9.2).

## 11.2 Access Specifiers for Base Classes

If a class is declared to be a base class (§10) for another class using the public access specifier, the public members of the base class are public members of the derived class and protected members of the base class are protected members of the derived class. If a class

is declared to be a base class for another class using the private access specifier, the public and protected members of the base class are private members of the derived class. Private members of a base class remain inaccessible even to derived class members unless friend declarations within the base class declaration are used to explicitly grant access. protected cannot be used as the access-specifier in a base-specifier for a base class.

In the absence of an access-specifier for a base class, public is assumed when the derived class is declared struct and private is assumed when the class is declared class. For example:

```
class D1 : private base { ... };
class D2 : public base { ... };
class D3 : base { ... }; // 'base' private by default
struct D4 : public base { ... };
struct D5 : private base { ... };
struct D6 : base { ... }; // 'base' public by default
```

Here base is a public base of D2 and D4, and D6, and a private base of D1, D3, and D5.

#### 11.3 Access Declarations

The access to a member of a base class in a derived class can be adjusted by mentioning its qualified-name in the public or protected part of a derived class declaration. Such mention is called an access declaration.

For example:

```
class base {
    int a;
public:
    int b, c;
    int bf();
class derived : private base {
    int d;
public:
    base::c; // adjust access to 'base::c'
    int e;
    int df();
};
int ef(derived&);
```

The external function ef can use only the names c, e, and df. Being a member of derived, the function df can use the names b, c, bf, d, e, and df, but not a. Being a member of base, the function bf can use the members a, b, c, and bf.

This notation may not be used to prevent access to a member that is accessible in the base class, nor may it be used to enable access to a member that is not accessible in the base class. For example:

```
class B {
public:
      int a;
private:
      int b;
protected:
      int c;
class D : private B {
public:
      B::a; // make 'a' a public member of D
      B::b; // make 'b' a public member of D
             // error: attempt to grant access
protected:
      B::c; // make 'a' a protected member of D
      B::a; // make 'a' a protected member of D
             // error: attempt to reduce access
```

An access declaration for the name of an overloaded function adjusts the access to all functions of that name in the base class.

#### 11.4 Friends

A friend of a class is a function that is not a member of the class but is permitted to use the private and protected member names from the class. A friend is not in the scope of the class and is not called with the member access operators (§5.2.4) unless it is a member of another class. The following example illustrates the differences between members and friends:

```
class X {
      int a;
      friend void friend_set(X*, int);
public:
      void member_set(int);
};
void friend_set(X* p, int i) { p->a = i; }
void X::member set(int i) { a = i; }
X obj;
friend_set(&obj,10);
obj.member set(10);
```

Friend declarations are not affected by access-specifiers (§9.2).

When a friend declaration refers to an overloaded name or operator, only the function specified by the argument types becomes a friend. A member function of a class X can be a friend of a class Y. For example,

```
class X {
      friend char* Y::foo(int);
      // ...
```

All the functions of a class x can be made friends of a class x by a single declaration using an elaborated-type-specifier (§9.1):

```
class Y {
      friend class X;
      // ...
```

If a class mentioned as a friend has not been declared its name is entered in the same scope as the name of the class containing the friend declaration (§9.1).

A friend function defined in a class declaration is inline and the re-writing rule specified for member functions (§9.3.2) is applied.

Friendship is inherited but not transitive. For example:

```
class A {
friend B;
      int a;
class B {
friend C;
};
class C {
      void f(A* p) { p->a++; } // error
};
```

#### 11.5 Protected Member Access

A friend or a member function of a derived class can access any public or protected static member of a publicly derived base class. A friend or a member function of a derived class can access a protected non-static member of a base class only through a pointer to, reference to, or object of the derived class of which it is a friend or member (and pointers to, references to, and objects of classes publicly derived from this class). For example:

```
class B {
protected:
    int i;
};
class D1 : public B {
class D2 : public B {
    friend void fr(B*,D1*,D2*);
    void mem(B*,D1*);
};
void fr(B* pb, D1* p1, D2* p2)
{
    pb \rightarrow i = 1; // illegal
    p1->i = 2; // illegal
    p2->i = 3; // ok (access through a D2)
```

## 11.6 Access to Virtual Functions

The access rules (§11) for a virtual function are determined by its declaration and are not affected by the rules for a function that later overrides it. For example:

```
class base {
public:
      virtual f();
};
class derived : public base {
private:
      f();
1:
void f()
      derived d;
      base* pb = &d;
      derived* pd = &d;
                       // ok: base::f() is public,
      pb->f();
                      // derived::f() is invoked
                       // error: derived::f() is private
      pd->f();
```

Access is checked at the call point.

## 11.7 Multiple Access

If a name can be reached through several paths through a multiple inheritance graph, the access is that of the path that gives most access. For example:

```
class W { public: f(); };
class A : private W { };
class B : public W { };
class C : public A, public B { f() { W::f(); } }; // ok
```

Since W::f() is available to C::f() along the public path through B access is legal.

# 12. Special Member Functions

Some member functions are special in that they affect the rules for how objects of a class are created, copied, and destroyed, and how values may be converted to values of other types. In many cases such special functions are called implicitly.

These member functions obey the usual access rules (§11). For example, declaring a constructor protected ensures that only derived classes and friends can create objects using

#### 12.1 Constructors

A member function with the same name as its class is called a constructor; it is used to construct values of its class type. If a class has a constructor, each object of that class will be initialized before any use is made of the object; see §12.6.

A constructor can be invoked for a const or volatile object even if it is not declared to be a const or volatile member function (§9.3.1). A constructor may not be virtual.

A default constructor for a class X is a constructor that can take no argument, that is, of the form X::X(). A default constructor will not be generated for a class X if any constructor has been declared for class X. A constructor that can be called with no arguments because of default arguments, for example X::X(int=0), is not a default constructor.

A copy constructor for a class X is a constructor that can be called to copy an object of class X; that is, one that can be called with a single argument of type x. For example, X::X(const  $X \in A$  and  $X : X(X \in A)$  are copy constructors. A copy constructor is only generated if needed (§12.8) and if no copy constructor is declared.

Constructors are not inherited. However, default constructors and copy constructors are generated (by the compiler) where needed (§12.8). Generated constructors are public.

A constructor for a class x may not take an argument of type x. For example, x: x(x) is illegal.

Constructors for array elements are called in increasing subscript order.

If a class has base classes or member objects with constructors, their constructors are called before the constructor for the derived class. The constructors for base classes are called first. See §12.6.2 for an explanation of how arguments can be specified for such constructors and how the order of constructor calls is determined.

An object of a class with a constructor cannot be a member of a union.

No return type (not even void) can be specified for a constructor. A return statement in the body of a constructor may not specify a return value. It is not possible to take the address of a constructor.

A constructor can be used explicitly to create new objects of its type, using the syntax

```
typedef-name ( argument-listopt )
For example,
      complex zz = complex(1,2.3);
      cprint( complex(7.8,1.2) );
```

An object created in this way is unnamed (unless the constructor was used as an initializer for a named variable as for zz above), with its lifetime limited to the expression in which it is created; see §12.2.

Member functions may be called from within a constructor; see §12.7.

## 12.2 Temporary Objects

When compiling C++ it is sometimes necessary and sometimes just convenient (for the compiler) to introduce a temporary variable. The use of such temporary variables is implementation dependent. When a compiler induces a temporary variable of a class that has a constructor then it must ensure that a constructor is called for the temporary variable. Similarly, the destructor must be called for an object of a class where a destructor is defined. For example,

Here, one might use a temporary in which to construct X(2) before passing it to f() by X(X&); alternatively, X(2) might be constructed in the space used to hold the argument for the first call of f(). Also, a temporary might be used to hold the result of f(X(2)) before copying it to b by X(X&); alternatively, f()'s result might be constructed in b. On the other hand, for many functions f(), the expression a=f(a) requires a temporary for either the argument a or the result of f(a) to avoid undesired aliasing of a.

The compiler must ensure that a temporary object is destroyed. There are only two things that can be done with a temporary: fetch its value (implicitly copying it) to use in some other expression, or bind a reference to it. If the value of a temporary is fetched, that temporary is then dead and can be destroyed immediately. If a reference is bound to a temporary, the temporary must not be destroyed until the reference is. This destruction must take place before exit from the scope in which the temporary is created.

Another form of temporaries is discussed in §8.4.3.

## 12.3 Conversions

Type conversions of class objects can be specified by constructors and by conversion functions.

Such conversions, often called *user-defined conversions*, are used implicitly in addition to standard conversions (§4). For example, an assignment to an object of class X is legal not only if the type T of the assigned value is X, but also if a conversion has been declared from T to X. User-defined conversions are used similarly for conversion of initializers (§8.4), function arguments (§5.2.2, §8.2.5), function return values (§6.6.3, §8.2.5), expression operands (§5), expressions controlling iteration and selection statements (§6.5, §6.4), and explicit type conversions (§5.2.3, §5.4).

See §13.2 for a discussion of the use of conversions in function calls as well as examples below.

A conversion may not be defined by both a constructor and a conversion function. For example:

```
class B;
class A {
     // ...
     A(const B&);
};
class B {
     // ...
     operator A(); // error: a conversion of a B to an A
                     // is already declared
};
```

### 12.3.1 Conversion by Constructor

A constructor taking a single argument specifies a conversion from its argument type to the type of its class. For example:

```
class X {
     // ...
     X(int);
     X(const char*, int = 0);
};
f(X arg) {
                   // a = X(1)
     X a = 1;
     X b = "asdf"; // b = X("asdf", 0)
                   // a = X(2)
     a = 2;
                   // f(X(3))
     f(3);
```

When no constructor for class X accepts the assigned type, no attempt is made to find other constructors to convert the assigned value into a type acceptable to a constructor for class X. For example:

```
class X { ... X(int); };
class Y { ... Y(X); };
Y a = 1;
                   // illegal: Y(X(1)) not tried
```

#### 12.3.2 Conversion Functions

A member function of a class X with a name of the form

```
conversion-function-name:
        operator conversion-type-name
conversion-type-name:
        type-specifiers ptr-operatoropt
```

specifies a conversion from X to the type specified by the conversion-type-name. Neither argument types nor return type may be specified. The type of a conversion function from a type F to a type T is T\*F::().

Conversion operators are inherited.

An example:

In all three cases the value assigned will be converted by X::operator int(). User-defined conversions are not restricted to use in assignments and initializations. For example:

```
X a, b;
// ...
int i = (a) ? 1+a : 0;
int j = (a&&b) ? a+b : i;
```

At most one user-defined conversion (constructor or conversion function) is implicitly applied to a single value. For example:

#### 12.4 Destructors

A member function of class cl named ~cl is called a destructor; it is used to destroy values of type cl immediately before the object containing them is destroyed. It takes no arguments, and no return type can be specified for it. A destructor can be invoked for a const object even if it is not declared to be a const member function (§9.3.1).

Base class destructors are implicitly executed after the destructors for their derived classes. Destructors for non-virtual base classes are executed in reverse order of their declaration in the derived class. Destructors for virtual base classes are executed after destructors for non-virtual base classes in the reverse order of their appearance in a depth-first left-to-right traversal of the directed acyclic graph of base classes. Member destructors are implicitly executed in reverse order of their declaration in the class they are members of. A destructor for a member object is executed after the destructor for the object it is a member of. This rule applies recursively for virtual bases of virtual bases.

Destructors are not inherited. A destructor calling destructors for bases and members are generated for a derived class. Generated destructors are public.

Destructors for elements of an array are called in reverse order of their construction.

A destructor may be virtual.

It is not possible to take the address of a destructor.

Member functions may be called from within a destructor; see §12.7.

An object of a class with a destructor cannot be a member of a union.

Destructors are invoked implicitly when an auto (§3.5) or temporary (§12.2, §8.4.3) object goes out of scope and for static (§3.5) objects at program termination (§3.4). They can be invoked through use of the delete operator (§5.3.4) for objects allocated by the new operator (§5.3.3) and explicitly using the destructor's fully qualified name. When invoked by the delete

operator, memory is freed by the destructor for the most derived class (§12.6.2) of the object using an operatordelete() (§5.3.4). For example,

```
class X { /* ... */ ~X(); };
void* operator new(size_t, void* p) { return p; }
void f(X* p);
static char buf[sizeof(X)];
void g()
      X* p = new X(args);
                             // allocate and initialize
      f(p);
      delete p;
                              // cleanup and deallocate
     p = new(&buf) X(args); // use buf[] and initialize
     p->X::~X();
                              // cleanup
```

Explicit calls of destructors are only necessary for objects placed at specific addresses using a new operator as shown in the example. Such use of explicit placement and destruction of objects can be necessary to cope with dedicated hardware resources and for writing memory management facilities.

#### 12.5 Free Store

When a class object is created with the new operator, an operator new() function is (implicitly) used to obtain the store needed (§5.3.3).

An X:: operator new() for a class X is a static member (even if not explicitly declared static). Its first argument must be of type size t, an implementation dependent integral type defined in the standard header < stddef.h>; it must return void\*. For example:

```
class X {
      // ...
      void* operator new(size_t);
      void* operator new(size t, arena*);
} ;
```

See §5.3.3 for the rules for selecting an operator new().

An X:: operator delete() for a class X is a static member (even if not explicitly declared static) and must have its first argument of type void\*; a second argument of type size t may be added. It cannot return a value; its return type must be void. For example

```
class X {
      // ...
      void operator delete(void*);
class Y {
      // ...
      void operator delete(void*, size t);
};
```

If the two argument style is used, operator delete() will be called with a second argument indicating the size of the object being deleted. The size passed is determined by the (static)

type of the pointer being deleted; that is, it will be correct either if the type of the pointer argument to the delete operator is the exact type of the object (and not, for example, just the type of base class) or if the type is that of a base class with a virtual destructor and a destructor was defined for the derived class.

The return type of the operator delete() used determines the type of a delete expression (§5.3.4).

The global operator new() and operator delete() are used for arrays of class objects. The number of elements must be specified when deleting an array (§5.3.3, §5.3.4). For example:

```
class X { ... ~X(); };
X* p = new X[size];
delete[size] p;
```

The size argument is assumed to be the number of elements in the array. What happens if this is not the case is undefined.

Since X::operator new() and X::operator delete() are static they cannot be virtual.

#### 12.6 Initialization

An object of a class with no constructors, no private or protected members, no virtual functions, and no base classes can be initialized using an initializer list; see §8.4.1. An object of a class with a constructor must be either initialized or have a default constructor (§12.1). The default constructor is used for objects that are not explicitly initialized.

### 12.6.1 Explicit Initialization

Objects of classes with constructors (§12.1) can be initialized with a parenthesized expression list. This list is taken as the argument list for a call of a constructor doing the initialization. Alternatively a single value is specified as the initializer using the = operator. In this case, its value is used as the initial value for the object if it is of the object's class or of a class publicly derived from that class; otherwise it is used as an argument to a constructor. For example:

```
class complex {
public:
        complex();
        complex(double);
        complex(double,double);
        // ...
};
complex sqrt(complex,complex);
```

```
// initialize by a call of
complex a(1);
                         // complex::complex(double)
complex b = a;
                        // initialize by a copy of 'a'
complex c = complex(1,2); // initialize by a call of
                         // complex::complex(double, double)
complex d = sqrt(b,c); // initialize by a call of
                        // sqrt (complex, complex);
                        // initialize by a call of
complex e;
                        // complex::complex()
                        // initialize by a call of
complex z = 3;
                         // complex::complex(double)
```

Overloading of the assignment operator = has no effect on initialization. If a copy constructor (§12.1) exists, it will be invoked when an object is initialized with another object of that class (as for b above), but not when an object is initialized with a constructor (as for c above).

Arrays of objects of a class with constructors use constructors in the initialization (§12.1) just like individual objects. If there are fewer initializers in the list than elements in the array, the default constructor (§12.1) is used. If there is no default constructor the initializer-list must be complete. For example,

```
complex cc = { 1, 2 }; // error; use constructor
complex v[6] = \{ 1, complex(1,2), complex(), 2 \};
```

Here, v[0] and v[3] are initialized with complex::complex(double), v[1] are initialized with complex::complex(double, double), and v[2], v[4], and v[5] are initialized with complex::complex().

An object of class M can be a member of a class X only (1) if M does not have a constructor, or (2) if M has a default constructor, or (3) if X has a constructor that specifies a ctor-initializer (§12.6.2) for that member. In case 2 the default constructor is called when the aggregate is created. If a member of an aggregate has a destructor then that destructor is called when the aggregate is destroyed.

Constructors for non-local static objects are called in the order they occur in a file; destructors are called in reverse order. See also §3.4, §6.7, §9.4.

## 12.6.2 Initializing Bases and Members

Initializers for base classes and for members may be specified in the definition of a constructor. This is most useful for class objects, constants, and references where the semantics of initialization and assignment differ. A ctor-initializer has the form

```
ctor-initializer:
         : mem-initializer-list
mem-initializer-list:
        mem-initializer
        mem-initializer, mem-initializer-list
mem-initializer:
        class-name ( expression-listopt )
        identifier ( expression-listopt )
```

The argument list is used to initialize the named non-static member or base class object. This is the only way to initialize const and reference members. For example:

```
struct basel { basel(int); ... };
struct base2 { base2(int); ... };
struct derived : base1, base2 {
     derived(int);
     basel b;
      const c;
};
derived::derived(int a)
: base2(a+1), base1(a+2), c(a+3), b(a+4)
{ /* ... */ }
derived d(10);
```

First, the base classes are initialized in declaration order (independent of the order of meminitializers), then the members are initialized in declaration order (independent of the order of mem-initializers), then the body of derived::derived() is executed (§12.1). The declaration order is used to ensure that sub-objects and members are destroyed in the reverse order of initialization.

Virtual base classes constitute a special case. A virtual base is constructed before any of its derived classes. Virtual bases are constructed before any non-virtual bases and in the order they appear on a depth-first left-to-right traversal of the directed acyclic graph of base classes. This rule applies recursively for virtual bases of virtual bases.

A complete object is an object that is not a sub-object representing a base class. Its class is said to be the most derived class for the object. All sub-objects for virtual base classes are initialized by the constructor of the most derived class. If a constructor of the most derived class does not specify a mem-initializer for a virtual base class then that virtual base class must have a default constructor or no constructors. Any mem-initializers specified in a constructor for a class that is not the class of the complete object are ignored. For example:

```
class V { public: V(); V(int); /* ... */ };
class A : public virtual V { public: A(); A(int); /* ... */ };
class B : public virtual V { public: B(); B(int); /* ... */ };
class C : public A, public B { public: C(); C(int); /* ... */ };
A::A(int i) : V(i) { /* ... */ }
B::B(int i) { /* ... */ }
C::C(int i) { /* ... */ }
          // use V(int)
V v(1);
          // use V(int)
A a(2);
         // use V()
B b(3);
C c(4);
          // use V()
```

A mem-initializer is evaluated in the scope of the constructor in which it appears. For example,

```
class X {
      int a;
public:
      const int& r;
      X(): r(a) {}
```

initializes X::r to refer to X::a for each object of class X.

#### 12.7 Constructors and Destructors

Member functions may be called in constructors and destructors. This implies that virtual functions may be called (directly or indirectly). The function called will be the one defined in the constructor's (or destructor's) own class or its bases, but not any function redefining it in a derived class. This ensures that unconstructed objects will not be accessed during construction or destruction. For example:

```
class X {
public:
      virtual void f();
      X() { f(); } // calls X::f()
      ~X() { f(); } // calls X::f()
};
class Y : public X {
      int& r;
      void f() { r++; } // disaster if r is uninitialized
      Y(int& rr) :r(rr) {}
};
```

A constructor for an abstract class may not call a member function for the object for which it was invoked.

## 12.8 Copying Class Objects

A class object can be copied in two ways, by assignment (§5.17) and by initialization (§12.1, §8.4, including function argument passing (§5.2.2) and function value return (§6.6.3)). Conceptually, for a class X these two operations are implemented by an assignment operator and a copy constructor (§12.1). The programmer may define one or both of these. If not defined by the programmer, they will be defined as member-wise assignment and memberwise initialization of the members of X, respectively.

If all bases and members of a class x have copy constructors accepting const arguments the generated copy constructor for X will take a single argument of type const X&:

```
X::X(const X&)
```

otherwise it will take a single argument of type X&:

```
X::X(X&)
```

and copying of const X objects will not be possible.

Similarly, if all bases and members of a class X have assignment operators accepting const arguments the generated assignment operator for X will take a single argument of type const X& :

```
X& X::operator=(const X&)
```

otherwise it will take a single argument of type X&:

```
X& X::operator=(X&)
```

and copying of const X objects will not be possible. The default assignment operator will return a reference to the object for which is is invoked. Generated assignment operators are public.

Using member-wise assignment and member-wise initialization implies that if a class X has a member of a class M, M's assignment operator and M's copy constructor are used to implement assignment and initialization of the member, respectively. If a class has a constant member, a reference member, or a member of a class with a private operator=(), the default

assignment operation cannot be generated. Similarly, if a member of a class M has a private copy constructor then the default copy constructor cannot be generated.

The default assignment and copy constructor will be declared, but they will not be defined (that is, a function body generated) unless actually needed. That is, X::operator=() will be generated only if no assignment operation is explicitly declared and an object of class X is actually assigned an object of class X or an object of a class derived from X or if the address of X::operator= is taken. Initialization is handled similarly.

If generated, assignment and copy constructor will be public members and the assignment operator for a class X will be defined to return a reference of type X& referring to the object assigned to.

If a class X has any X::operator=() defined, even one that takes an argument of a type unrelated to X, X::operator=(const X&) will not be generated. If a class has any copy constructor defined, X(const X&) will not be generated. For example:

Assignment of class objects of class X is defined in terms of X::operator(const X&). This implies that objects of a derived class can be assigned to objects of a public base class. For example:

```
class X {
public:
    int b;
};

class Y : public X {
public:
    int c;
};

void f()
{
    X x1;
    Y y1;

    x1 = y1;  // ok
    y1 = x1;  // error
}
```

Here y1.b is assigned to x1.b and y1.c is not copied.

Copying one object into another using the default copy constructor of the default assignment operator does not change the structure of either object. For example:

```
struct s {
     virtual f();
      // ...
};
struct ss : public s {
     f();
     // ...
};
void f()
     sa;
     ss b;
     a = b; // really a.s::operator=(&b)
     b = a; // error
     a.f(); // calls s::f
     b.f(); // calls ss::f
```

The call a.f() will invoke s::f() (as is suitable for an object of class s (§10.2)) and the call b.f() will call ss::f() (as is suitable for an object of class ss).

An object of a class X with a constructor cannot be passed as an argument to a function that does not supply an appropriate argument declaration (§8.2.5). For example,

```
class X {
     // ...
     X (X&);
};
int f(int ...);
void g(X a)
               // error: no formal argument for object
     f(1,a);
             // of class with copy constructor
}
```

## 13. Overloading

When several different function declarations are specified for a single name in the same scope, that name is said to be overloaded. When that name is used, the correct function is selected by comparing the types of the actual arguments with the formal argument types. For example,

```
double abs (double);
int abs(int);
             // call abs(int);
abs(1);
            // call abs(double);
abs (1.0);
```

Since for any type T, a T and a T& accept the same set of initializers, functions with argument types differing only in this respect may not have the same name. For example,

```
int f(int i) { /* ... */ }
                           // error: function types
int f(int& r) { /* ... */ }
                              // not sufficiently different
```

Similarly, since for any type T, a T, a const T, and a volatile T accept the same set of initializers, functions with argument types differing only in this respect may not have the same name. It is, however, possible to distinguish between const T&, volatile T&, and plain T& so functions that differ only in this respect may be defined.

Functions that differ only in the return type may not have the same name.

Member functions that differ only in that one is a static member and the other isn't may not have the same name (§9.4).

A typedef is not a separate type, but only a synonym for another type (§7.1.3). Therefore, functions that differ by typedef "types" only may not have the same name. For example,

```
typedef int Int;
f(int i) { /* ... */ }
f(Int i) { /* ... */ } // error: redefinition of f
```

Enumerations, on the other hand, are distinct types and can be used to distinguish overloaded functions. For example,

```
enum E { a };
f(int i) { /* ... */ }
f(E i) { /* ... */ }
```

Argument types that differ only in a pointer \* vs an array [] are identical. Note that only the second and subsequent array dimensions are significant in argument types (§8.2.4):

```
f(char*);
f(char[]); // same as f(char*);
f(char[7]); // same as f(char*);
f(char[9]); // same as f(char*);
g(char(*)[10]);
g(char[5][10]); // same as g(char(*)[10]);
g(char[7][10]); // same as g(char(*)[10]);
g(char(*)[20]); // different from g(char(*)[10]);
```

## 13.1 Declaration Matching

Two function declarations of the same name refer to the same function if they are in the same scope and have identical argument types (§13). A function member of a derived class is not in the same scope as a function member of the same name in a base class. For example,

```
class B {
      public:
            int f(int);
      };
      class D : public B {
      public:
            int f(char*);
      };
Here D::f(char*) hides B::f(int) rather than overloading it. So:
      void h (D* pd)
      1
                              // error: D::f(char*) hides B::f(int)
            pd->f(1);
                              // ok
            pd->B::f(1);
            pd->f("asdf"); // ok, calls D::f
```

A locally declared function is not in the same scope as a function in file scope.

```
int f(char*);
void g()
      extern f(int);
      f("asdf"); // error: f(int) hides f(char*)
                  // so there is no f(char*) in this scope
```

Different versions of an overloaded member function may be given different access rules. For example:

```
class buffer {
private:
      char* p;
      int size;
protected:
      void buffer(int sz, char* store) { size = sz; p = store; }
public:
      void buffer(int sz) { p = new char[size = sz]; }
      // ...
};
```

## 13.2 Argument Matching

A call of a given function name chooses, from among all functions by that name that are in scope, the function that best matches the actual arguments. The best-matching function is the intersection of sets of functions that best match on each argument. Unless this intersection has exactly one member, the call is illegal.

For purposes of argument matching, a function with n default arguments (§8.2.6) is considered to be n+1 functions with different numbers of arguments.

For purposes of argument matching, a non-static member function is considered to have an extra argument specifying the object for which it is called. This extra argument requires a match by either the object or pointer specified in the explicit member function call notation

(§5.2.4) or by the first operand of an overloaded operator (§13.4). Where the member function is explicitly called for a pointer using the -> operator, this extra argument is assumed to have type const x\* for const members and X\* for others. Where the member function is explicitly called for an object using the . operator or the function is invoked for the first operand of an overloaded operator (§13.4), this extra argument is assumed to have type const X& for const members and X& for others.

An ellipsis in a formal argument list (§8.2.5) is a match for an actual argument of any type except a type T for which T (T&) exists.

A function matches on an argument only if there exists an admissible sequence of conversions leading from the type of the actual argument to the type of the corresponding formal argument. A sequence is admissible unless it contains an admissible subsequence or more than one user-defined conversion. A best-matching sequence is an admissible sequence for which no better admissible sequence exists.

For example, int->float->double is a sequence of conversions from int to double, but it is not an admissible sequence because it contains the shorter admissible sequence int->double; thus the rule against admissible sub-sequences ensures that only shortest sequences of conversions are ever considered.

Except as mentioned below, the following trivial conversions involving a type T do not affect which of two conversion sequences is better:

from:		to:	
	T		T&
	T&		T
	T[]		T*
	T(args)		(*T) (args)
	T		const T
	T		volatile T

Sequences of trivial conversions that differ only in order are indistinguishable.

A temporary variable is needed for a formal argument of type T& if the actual argument is not an Ivalue, has a type different from T, or is a const and T isn't. In this case, a conversion of a T to a T& is not a trivial conversion but a conversion requiring a temporary (see [4] below).

Sequences of conversions are considered according to these rules:

- [1] Exact match: Sequences of zero or more trivial conversions are better than all other sequences. Of these, those that do not convert T\* to const T\*, T\* to volatile T\*, T& to const T\$, or T\$ to volatile T\$ are better than those that do.
- [2] Match with promotions: Of sequences not mentioned in [1], those that contain only integral promotions (§4.1), conversions from float to double, and trivial conversions are better than all others.
- [3] Match with standard conversions: Of sequences not mentioned in [2], those with only standard (§4) and trivial conversions are better than all others. Of these, if B is publicly derived directly or indirectly from A, converting a B\* to A\* is better than converting to void\* or const void\*; further, if C is publicly derived directly or indirectly from B, converting a C\* to B\* is better than converting to A\* and converting a C\* to B\* is better than converting to A\*.
- [4] Match with conversions requiring temporaries: Of sequences not mentioned in [3], those that involve only conversions to T& requiring the use of temporary values (§8.4.3), user-defined (§12.3), standard (§4) and trivial conversions are better than all other sequences.
- [5] Match with user-defined conversions: Of sequences not mentioned in [4], those that involve only user-defined conversions (§12.3), conversions to T& requiring the use of temporary values (§8.4.3), standard (§4) and trivial conversions are better than all other sequences.

[6] Match with ellipsis: Sequences that involve matches with the ellipsis are worse than all others.

#### 13.2.1 Examples

Consider

```
f(char&);
f(short);
f(char*);
void g()
     f('c'); // call f(char&);
     char v[10];
                // call f(char*);
     f(v);
     const char ch = 'c';
     f(ch); // call f(char&);
     f(3); // call f(short);
}
```

Here, temporary variables are needed for the first call of f() because 'c' is a literal (of type char) and also for the third call because ch is a const char rather than the required char. Since f(3) can be interpreted as a call of f(short) without the use of a temporary variable, f(short) is preferred to f(char&) which requires the use of a temporary.

Note that 0 is of type int so that it is an exact match on an int argument but a match with standard conversions on arguments of types short, double, char\*, etc.:

```
int f(char);
int f (double);
void g(short si)
     f('a');
               // matches f(char)
               // ambiguous: the int 0 can be converted
     f(0);
                // to either char or double
     f(si);
                // ambiguous: si can be converted
                // to either char or double
     f(1.0f); // matches f(double)
```

The last call is not ambiguous because the promotion from float to double is better than the standard conversion of a float to a char.

Integral promotions (§4.1) are implementation dependent:

```
int f(int);
int f (unsigned);
void g(unsigned short us)
      int i = f(us);
```

Here f (int) is called if size of (short) < size of (int); otherwise f (unsigned) is called.

Enumerators are of the type of their enumeration (§7.2) and can be used in overloaded function calls:

It is possible to declare two functions that differ only in const in a pointer or reference argument:

```
void f(const int*);
void f(int*);

void g(const int a, int b) {
    f(&a);    // calls f(const int*)
    f(&b);    // calls f(int*)
}
```

This is especially important in the case of const objects and const member functions:

An inheritance hierarchy defines a preference order for the standard pointer and reference conversions (§4.6, §4.7):

```
class A {};
class B : public A {};
class C : public B {};

void g(A*);
void g(B*);
C cc;

void f()
{
      g(&cc);  // ok: call g(B*)}
```

In a sense, void\* is the root of such hierarchies:

```
void h(void*);
void h(A*);
void hh()
     h(&cc); // ok: call h(A*)
     h(0); // error: ambiguous
```

Standard conversions (§4) may be applied to the argument for a user-defined conversion, and to the result of a user-defined conversion:

```
struct S { S(long); operator int(); };
int f(long), f(char*);
int g(S), g(char*);
int h(S&), h(char*);
void k(S& a)
      f(a); // f(long(a.operator int()))
      g(1); // g(S(long(1)))
      h(1); // h(S(long(1)))
```

If user-defined coercions are needed for an argument, no account is taken of any standard coercions that might also be involved. For example,

```
class x {
public:
      x(int);
};
class y {
public:
      y(long);
extern f(x);
extern f(y);
void g()
1
    f(1); // ambiguous
```

The call f(1) is ambiguous despite f(y(long(1))) needing one more standard conversion than f(x(1)).

If different combinations of standard or user-defined conversions are possible, the call is ambiguous:

```
extern f(int,long);
extern f(long,int);

void g()
{
    f(3,4);  // ambiguous
}
```

A call needing only standard conversions is preferred over one requiring user-defined conversions:

However, where identical conversions exist for an argument, matching is determined by other arguments (if any):

No preference is given to conversion by constructor (§12.1) over conversion by conversion function (§12.3.2) or vice versa:

Default arguments can cause ambiguities:

```
int f();
     int f(int i = 1);
     void g()
     {
          f(11); // fine
          f();
                // error, ambiguous: f() or f(1)
The ellipsis (...) can also cause ambiguities:
    f(int);
    f(int ...);
    f(int, char* ...);
    void g()
     1
         f(1, "asdf",2); // fine: f(int, char* ...)
     ł
```

## 13.3 Address of Overloaded Function

A use of a function name without arguments picks out, among all functions of that name that are in scope, the (only) function that matches the target, which may be

```
an object being initialized (§8.4)
a parameter of a function (§5.2.2)
a parameter of a user-defined operator (§13.4)
the right side of an assignment (§5.17)
```

Note that if f() and g() are both overloaded functions, the cross product of possibilities must be considered to resolve f(&g), or the equivalent expression f(g).

For example:

```
int f(double);
int f(int);
int (*pfd) (double) = &f;
int (*pfi)(int) = &f;
int (*pfa)(...) = &f; // error: type mismatch
```

The last initialization is an error because no f() with type int(...) has been defined, and not because of any ambiguity.

Note also that there are no standard conversions (§4) of one pointer to function type into another (§4.6). In particular, even if B is a public base of D we have:

```
D* f();
B^* (*p1)() = &f; // error
void g(D*);
void (*p2)(B*) = &g; // error
```

## 13.4 Overloaded Operators

Most operators can be overloaded.

The last two operators are function call (§5.2.2) and subscripting (§5.2.1).

Both the unary and binary forms of

+ - \*

can be overloaded.

The following operators cannot be overloaded:

.\* :: ?:

nor can the preprocessing symbols # and ## (§16).

Operator functions are usually not called directly; instead they are invoked to implement operators (§13.4.1, §13.4.2). They can be explicitly called, though. For example:

The operators new and delete are described in §5.3.3 and §5.3.4 and the rules described below in this section do not apply to them.

An operator function must either be a member function or take at least one argument of class type. It is not possible to change the precedence, grouping, or number of operands of operators. The pre-defined meaning of the operators = and (unary) & applied to class objects may be changed. With the exception of operator=() operator functions are inherited; see §12.8 for a description of the rules for operator=().

Identities among operators applied to basic types (for example  $++a \equiv a+=1$ ) need not hold for operators applied to class types. Some operators, for example assignment, require an operand to be an Ivalue when applied to basic types; this is not required when the operators are declared for class types.

## 13.4.1 Unary Operators

A unary operator, whether prefix or postfix, may be declared by a non-static member function (§9.3) taking no arguments or a non-member function taking one argument. Thus, for any unary operator @, both x@ and @x can be interpreted as either x.operator@() or operator@(x). If both forms of the operator function have been declared, argument matching (§13.2) determines which, if any, interpretation is used. When the operators ++ and -- are overloaded, it is not possible to distinguish prefix application from postfix application from within the overloading function.

### 13.4.2 Binary Operators

A binary operator may be declared either by a non-static member function (§9.3) taking one argument or by a non-member function taking two arguments. Thus, for any binary operator 0,  $x \in y$  can be interpreted as either x. operator (y) or operator (x, y). If both forms of the operator function have been declared, argument matching (§13.2) determines which, if any, interpretation is used.

### 13.4.3 Assignment

The assignment function operator=() must be a non-static member function; it is not inherited (§12.8). Instead, unless the user defines operator= for a class X, operator= is defined, by default, as memberwise assignment of the members of class X:

```
X& X::operator=(const X& from)
      /* copy members of X */
```

#### 13.4.4 Function Call

Function call

```
primary-expression ( expression-listont )
```

is considered a binary operator with the primary-expression as the first operand and the possibly empty expression-list as the second. The name of the defining function is operator(). Thus, a call x(arg1,arg2,arg3) is interpreted as x.operator()(arg1,arg2,arg3) for a class object x. operator() must be a non-static member function.

## 13.4.5 Subscripting

Subscripting

```
primary-expression [ expression ]
```

is considered a binary operator. A subscripting expression x[y] is interpreted as x.operator[] (y) for a class object x. operator[] must be a non-static member function.

#### 13.4.6 Class Member Access

Class member access using ->

```
primary-expression -> primary-expression
```

is considered a unary operator. An expression  $x\rightarrow m$  is interpreted as  $(x.operator\rightarrow ())$ >m for a class object x. It follows that operator->() must either return a pointer to a class object or an object of a class for which operator->() is defined. operator-> must be a non-static member function.

# 14. Templates (experimental)

<< The template design is experimental; see Bjarne Stroustrup: Parameterized Types for C++, Proc. USENIX C++ Conference, Denver, October, 1988. >>

# 15. Exception Handling (experimental)

<< The exception handling design is experimental >>

# 16. Compiler Control Lines

This section will be replaced with one based on the preprocessing defined for ANSI C. The obvious adjustment for the additional C++ keywords and tokens will be made. C++ style comments will be added so that the two styles of comments can be used to comment out each other as described in (§2.2), so that macro expansion will not take place within // comments, and so that // style comments appearing in macro definitions will be turned into whitespace before the macro is expanded.

The compiler contains a preprocessor capable of macro substitution, conditional compilation, and inclusion of named files.

The name cplusplus is defined when compiling a C++ program.

Lines beginning with # communicate with this preprocessor. These lines have syntax independent of the rest of the language; they may appear anywhere and have effect which lasts (independent of scope) until the end of the source program file.

Note that const and inline definitions provide alternatives to many uses of #define.

## 16.1 Token Replacement

A compiler-control line of the form

#define identifier token-string

causes the preprocessor to replace subsequent instances of the identifier with the given string of tokens. Semicolons in, or at the end of, the token-string are part of that string. A line of the form

#define identifier ( identifier , ... , identifier ) token-string

where there is no space between the first identifier and the (, is a macro definition with arguments. Subsequent instances of the first identifier followed by a (, a sequence of tokens delimited by commas, and a) are replaced by the token string in the definition. Each occurrence of an identifier mentioned in the formal argument list of the definition is replaced by the corresponding token string from the call. The actual arguments in the call are token strings separated by commas; however commas in quoted strings or protected by parentheses do not separate arguments. The number of formal and actual arguments must be the same. Strings and character constants in the token-string are scanned for formal arguments, but strings and character constants in the rest of the program are not scanned for defined identifiers.

In both forms the replacement string is rescanned for more defined identifiers. In both forms a long definition may be continued on another line by writing \ at the end of the line to be continued. A control line of the form

#undef identifier

causes the identifier's preprocessor definition to be forgotten.

#### 16.2 File Inclusion

A compiler control line of the form

#include "filename"

causes the replacement of that line by the entire contents of the file *filename*. The named file is searched for first in the directory of the original source file, and then in a sequence of specified or standard places. Alternatively, a control line of the form

#include <filename>

searches only the specified or standard places, and not the directory of the source file. (How the places are specified is not part of the language.)

#include's may be nested.

## 16.3 Conditional Compilation

A compiler control line of the form

#if expression

checks whether the expression evaluates to non-zero. The expression must be a constant expression (§12). In addition to the usual C++ operations a unary operator defined can be used. When applied to an identifier, its value is non-zero if that identifier has been defined using #define and not later undefined using #undef; otherwise its value is 0. A control line of the form

#ifdef identifier

checks whether the identifier is currently defined in the preprocessor; that is, whether it has been the subject of a #define control line. A control line of the form

#ifndef identifier

checks whether the identifier is currently undefined in the preprocessor.

All three forms are followed by an arbitrary number of lines, possibly containing a control line

#else

and then by a control line

#endif

If the checked condition is true then any lines between #else and #endif are ignored. If the checked condition is false then any lines between the test and a #else or, lacking a #else, the #endif, are ignored.

These constructions may be nested.

#### 16.4 Line Control

For the benefit of other preprocessors that generate C++ programs, a line of the form

#line constant "filename" out

causes the compiler to believe, for purposes of error diagnostics, that the line number of the next source line is given by the constant and the current input file is named by the identifier. If the identifier is absent the remembered file name does not change.

## **Appendix A: Grammar Summary**

This appendix is not part of the C++ reference manual proper and does not define C++ language features.

This summary of C++ syntax is intended to be an aid to comprehension. It is not an exact statement of the language. In particular, this grammar accepts a superset of valid C++ constructs and the disambiguation rules (§6.8, §10.1.1) must be used to distinguish expressions from declarations and access control, ambiguity, and type rules must be used to weed out syntactically valid, but meaningless constructs.

## A.1 Key Words

New context-dependent keywords are introduced into a program by typedef (§7.1.3), class (§9), enumeration (§7.2), and template (§14) declarations:

class-name: identifier enum-name: identifier

typedef-name: identifier

Note that a typedef-name naming a class is also a class-name (§9.1).

## A.2 Expressions

expression: assignment-expression expression, assignment-expression assignment-expression: conditional-expression unary-expression assignment-operator assignment-expression assignment-operator: one of conditional-expression: logical-or-expression logical-or-expression ? expression : conditional-expression logical-or-expression: logical-and-expression logical-or-expression | | logical-and-expression logical-and-expression: inclusive-or-expression logical-and-expression && inclusive-or-expression inclusive-or-expression: exclusive-or-expression inclusive-or-expression | exclusive-or-expression

        goto identifier ;
declaration-statement:
        declaration
```

## A.7 Preprocessor

```
#define identifier token-string
  #define identifier ( identifier , ... , identifier ) token-string
  #else
  #endif
  #if expression
  #ifdef identifier
  #ifndef identifier
  #include "filename"
#include <filename>
  #line constant "filename" opt
  #undef identifier
```

## **Appendix B: Compatibility**

This appendix is not part of the C++ reference manual proper and does not define C++ language features.

C++ is based on C (K&R78) and adopts most of the changes specified by the draft ANSI C report. Converting programs among C++, K&R C, and ANSI C may be subject to vicissitudes of expression evaluation. All differences between C++ and ANSI C can be diagnosed by a compiler. With the following two exceptions, programs that are both C++ and ANSI C have the same meaning in both cases:

In C, sizeof('a') equals sizeof(int); in C++, it equals sizeof(char). In C, given

```
enum e { A };
```

sizeof(A) equals sizeof(int); in C++, it equals sizeof(e), which need not equal sizeof(int).

A structure name declared in an inner scope can hide the name of an object, function, enumerator, or type in an outer scope. For example,

#### **B.1 Extensions**

This section summarizes the major extensions to C provided by C++.

#### B.1.1 C++ Features Available in 1985

This subsection summarizes the extensions to C provided by C++ in the 1985 version of this manual:

The types of function arguments can be specified (§8.2.5) and will be checked (§5.2.2). Type conversions will be performed (§5.2.2). This is also in ANSI C.

Single-precision floating point arithmetic may be used for float expressions; §3.6.1 and §4.3. This is also in ANSI C.

Function names can be overloaded; §13.

Operators can be overloaded; §13.4.

Functions can be inline substituted; §7.1.1.

Data objects can be const; §7.1.6. This is also in ANSI C.

Objects of reference type can be declared; §8.2.2 and §8.4.3.

A free store is provided by the new and delete operators; §5.3.3, §5.3.4.

Classes can provide data hiding (§11), guaranteed initialization (§12.1), user-defined conversions (§12.3), and dynamic typing through use of virtual functions (§10.2).

The name of a class or enumeration is a type name; §9.

Any pointer can be assigned to a void\* without use of a cast; §4.6. This is also in ANSI C.

A declaration within a block is a statement; §6.7.

Anonymous unions can be declared; §9.5.

#### B.1.2 C++ Features Added Since 1985

This subsection summarizes the major extensions of C++ since the 1985 version of this manual:

A class can have more than one direct base class (multiple inheritance); §10.1.

Class members can be protected; §11.

Pointers to class members can be declared and used; §8.2.3, §5.5.

Operators new and delete can be overloaded and declared for a class; §5.3.3, §5.3.4, §12.5. This allows the "assignment to this" technique for class specific storage management to be removed to the anachronism section; §B.3.3.

Objects can be explicitly destroyed; §12.4.

Assignment and initialization are defined as member-wise assignment and initialization; §12.8.

The overload keyword was made redundant and moved to the anachronism section; §B.3.

General expressions are allowed as initializers for static objects; §8.4.

Data objects can be volatile; §7.1.6. Also in ANSI C.

Initializers are allowed for static class members; §9.4.

Member functions can be static; §9.4.

Member functions can be const and volatile; §9.3.1.

Linkage to non-C++ program fragments can be explicitly declared; §7.4.

Operators ->, ->\*, and , can be overloaded; §13.4.

Classes can be abstract; §10.3.

Templates (experimental); §14.

Exception handling (experimental); §15.

## B.2 C++ and ANSI C

In general, C++ provides more language features and fewer restrictions than ANSI C so most constructs in ANSI C are legal in C++ with their meanings unchanged. The exceptions are:

ANSI C programs using any of the C++ keywords

asm catch friend new private public this class delete inline operator protected template virtual

as identifiers are not C++ programs; §2.4.

Though deemed obsolescent in ANSI C, a C implementation may impose Draconian limits on the length of identifiers; a C++ implementation is not permitted to; §2.3.

In C++, a function must be declared before it can be called; §5.2.2.

The function declaration f(); means that f takes no arguments (§8.2.5); in C it means that f can take any number of arguments of any type at all. Such use is deemed obsolescent in ANSI C.

In ANSI C a global data object may be declared several times without using the extern specifier; in C++ it must be defined exactly once; §3.3.

In C++, a class may not have the same name as a typedef declared to refer to a different type in the same scope; §9.1.

In ANSI C a void\* may be used as the right-hand operand of an assignment to or initialization of a variable of any pointer type; in C++ it may not; §7.1.6.

C allows jumps to bypass an initialization; C++ does not.

In ANSI C, a global const by default has external linkage; in C++ it does not; §3.3.

"Old style" C function definitions and calls of undeclared functions are considered anachronisms in C++ and may not be supported by all implementations; §B.3.1. This is deemed obsolescent in ANSI C.

Enumerators declared within a struct are in the scope of the struct in C++ (§7.2) and in the scope enclosing the struct in ANSI C.

Assignment to an object of enumeration type with a value that is not of that enumeration type is considered an anachronism in C++ and may not be supported by all implementations; §7.2. ANSI C recommends a warning for such assignments.

Surplus characters are not allowed in strings used to initialize character arrays; §8.4.2.

The type of a character constant is char in C++ (§2.5.2) and int in C.

The type of an enumerator is the type of its enumeration in C++ (§7.2) and int in C.

In addition, the ANSI C standard allows conforming implementations to differ considerably; this may lead to further incompatibilities between C and C++ implementations. In particular, some C implementations may consider certain incompatible declarations legal. C++ requires consistency even across compilation boundaries; §3.3.

#### **B.2.1** How to Cope

In general, a C++ program uses many features not provided by ANSI C. In this case, the minor differences of §B.2 don't matter since they are dwarfed by the C++ extensions. Where ANSI C and C++ need to share header files, more care must be taken so that such headers are written in the common subset of the two languages:

No advantage must be taken of C++ specific features such as classes, overloading, etc.

A name should not be used both as a structure tag and as the name of a different type.

Functions taking no arguments should be declared f (void) and not simply f ().

Global consts must be declared explicitly static or extern.

Conditional compilation using the C++ predefined name \_\_cplusplus may be used to distinguish information to be used by an ANSI C program from information to be used by a C++ program.

Functions that are to be callable from both languages must be explicitly declared to have C linkage.

#### **B.3** Anachronisms

The extensions presented here may be provided by an implementation to make it easier to use C programs as C++ programs or to provide continuity from earlier C++ implementations. Note that each of these features has undesirable aspects. An implementation providing them should also provide a way for the user to ensure that they do not occur in a source file. A C++

implementation is not obliged to provide these features.

The word overload may be used as a decl-specifier (§7) in a function declaration or a function definition. In this case overload is a reserved word and cannot be used as an identifier.

The definition of a static data member of a class for which the default "all zeros initialization" (§9.4) applies may be omitted.

An old-style (i.e., pre-ANSI C) C preprocessor may be used.

An int may be assigned to an object of enumeration type.

The number of elements in an array may be left unspecified when deleting an array of a type for which there is no destructor; §5.3.4.

#### **B.3.1 Old Style Function Definitions**

The C function definition syntax

max(a,b) int b; { return (a<b) ? b : a; }

may be used. If a function defined like this has not been previously declared its argument type will be taken to be (...), that is, unchecked. If it has been declared its type must agree with that of the declaration.

Class member functions may not be defined with this syntax.

## **B.3.2** Old Style Base Class Initializer

In a mem-initializer(§12.6.2), the class-name naming a base class may be left out provided there is exactly one immediate base class. For example

causes the base constructor to be called with the argument i.

#### **B.3.3** Assignment to this

Memory management for objects of a specific class can be controlled by the user by suitable assignments to the this pointer. By assigning to the this pointer before any use of a member, a constructor can implement its own storage allocation. By assigning a zero value to

this, a destructor can avoid the standard de-allocation operation for objects of its class. Assigning a zero value to this in a destructor also suppressed the implicit calls of destructors for bases and members. For example:

```
class cl {
   int v[10];
   cl() { this = my_allocator( sizeof(cl) ); }
   ~cl() { my_deallocator( this ); this = 0; }
}
```

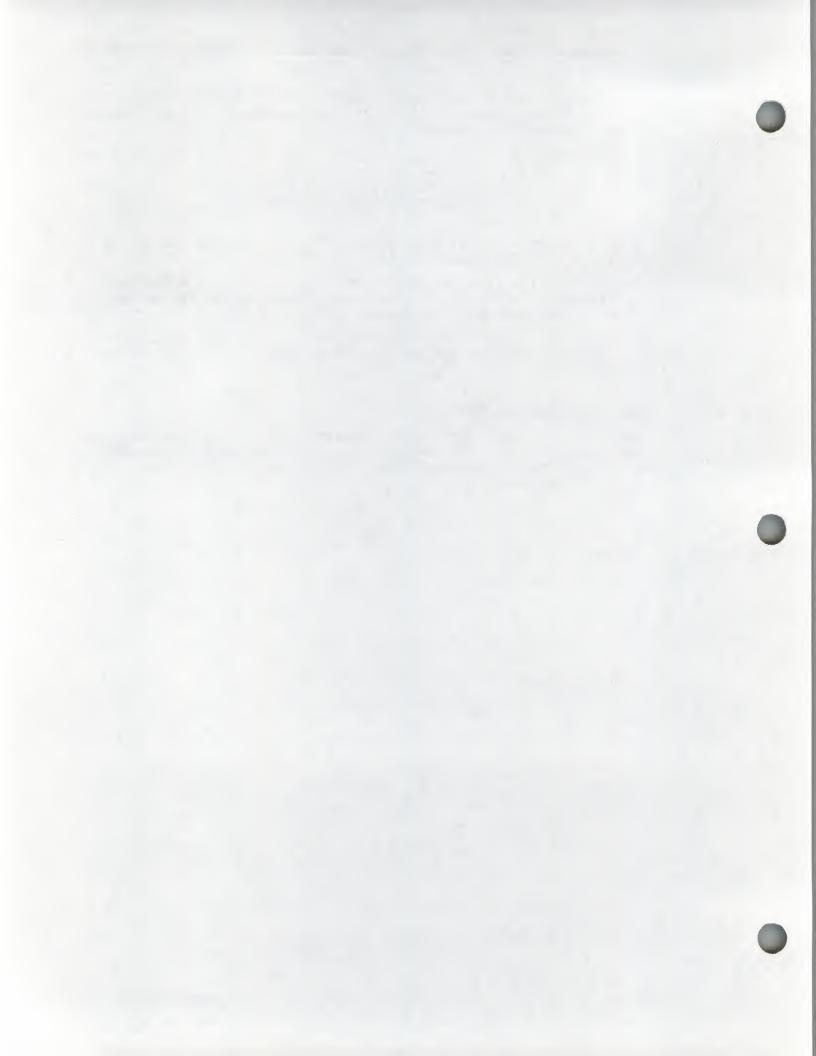

On entry into a constructor, this is non-zero if allocation has already taken place (as is the case for auto, static, and member objects) and zero otherwise.

Calls to constructors for a base class and for member objects will take place (only) after an assignment to this. If a base class's constructor assigns to this, the new value will also be used by the derived class's constructor (if any).

Note that if this anachronism exists the type of the this pointer either cannot be a \*const or the enforcement of the rules for assignment to a constant pointer must be subverted for the this pointer.

#### **B.3.4 Cast of Bound Pointer**

A pointer to member function for a particular object may be cast into a pointer to function, for example, (int(\*)())p->f. The result is a pointer to the function that would have been called using that member function for that particular object. Any use of the resulting pointer is — as ever — undefined.

Table of Contents

# **Appendix C: Implementation Specific Behavior**

This appendix describes implementation specific behavior of the AT&T C++ Language System. Implementation specific behaviors can be categorized as follows:

- 1. behavior that the Product Reference Manual defines as "implementation dependent"
- 2. behavior that depends on the underlying C compiler or preprocessor used with Release 2.0
- 3. properties that are defined in the standard header files stddef.h, limits.h, and stdlib.h
- 4. translation limits
- 5. language constructs that are not implemented in this release

This appendix addresses categories 1, 2, 4, and 5. For details about properties defined in the standard header files (category 3), see the headers themselves. Additional information about constructs that are not implemented is provided in Appendix D, which contains an alphabetical listing of the "not implemented" messages.

The ordering and numbering of sections in this appendix corresponds to the order and numbering of the related sections in the *Reference Manual*. The section entitled "Translation Limits", which does not have a corresponding section in the *Reference Manual*, precedes the numbered sections.

#### **Translation Limits**

Release 2.0 of the AT&T C++ Language System imposes the following translation limits:

- 50 nesting levels of compound statements
- 127 nesting levels of #included files
- 10 nesting levels of linkage declarations
- 4088 characters in a token
- 22222 virtual functions in a class
- 15000 identifiers generated by the implementation

These limits can be changed by recompiling the translator. Additional translation limits may be inherited from the underlying C compiler and preprocessor.

## 2.3 Identifiers (Names)

Identifiers reserved by Release 2.0: In addition to identifiers that contain a sequence of two underscores, Release 2.0 also reserves the identifiers reserved in the proposed ANSI C standard.

#### 2.5.2 Character Constants

Value of multicharacter constants: The Reference Manual states that the value of a multicharacter constant, such as 'abcd', is implementation dependent. Release 2.0 passes these constants to the underlying C compiler, which determines their values. A multicharacter constant containing more characters than sizeof(int) is reported as an error by Release 2.0.

Value of (single) character constants: The Reference Manual states that the value of a character constant is implementation dependent if it exceeds that of the largest char. Release 2.0 accepts octal and hexadecimal character literals that do not fit in a char. It uses the low order bits that make up the value of the constant. Thus, the octal character constant '\7777', for example, will be treated as '\377'. The hexadecimal character constant '\x123' will be treated as '\x23'.

Wide character constants: Release 2.0 does not implement wide character constants, such as L'ab'. A "not implemented" message is reported.

### 2.5.3 Floating Constants

Long double floating constants: When compiling with the +a0 option, Release 2.0 will remove an 1 or L suffix from a floating constant before passing the constant to the underlying C compiler. Under the +a1 option such a constant will be passed unchanged to the underlying C compiler. In either case, the constant will be considered to be of type long double for purposes of resolving overloaded function calls.

### 2.5.4 String Literals

Wide character strings: Release 2.0 does not implement wide character strings, such as L"abcd". A "not implemented" message is reported.

#### 3.4 Start and Termination

Type of main(): The Reference Manual states that the type of main() is implementation dependent. Release 2.0 itself does not impose any restrictions on the type of main(), but the underlying C compiler or the target environment may impose such restrictions.

## 3.6.1 Fundamental types

Signed integral types: Release 2.0 does not implement the type specifier signed; it issues a warning and proceeds as though the specifier signed had not appeared.

Long double type: When Release 2.0 is invoked with the +a0 option, the type long double will be the same size and precision as type double in the underlying C compiler. Under the +a1 option, long double will passed to the underlying C compiler as long double. In either case, type long double will be considered a distinct type for purposes of resolving overloaded function declarations and invocations.

#### 5. Expressions

Overflow and divide check: The *Reference Manual* states that the handling of overflow and divide check in expression evaluation is implementation dependent. Release 2.0 detects division by zero when the value of the denominator is known at compile time and issues a warning, but overflow and other divide check conditions are handled by the underlying C compiler and execution environment.

## 5.4 Explicit Type Conversion

Explicit conversions between pointer and integral types: The Reference Manual states that the value obtained by explicitly converting a pointer to an integral type large enough to hold it is implementation dependent. This behavior is defined by the underlying C compiler. Similarly, the behavior when explicitly converting an integer to a pointer depends on the underlying C compiler.

### 5.6 Multiplicative Operators

Sign of the remainder: The Reference Manual states that the sign of the result of the % operator is non-negative if both operands are non-negative; otherwise, the sign of the result is implementation dependent. This behavior depends on the underlying C compiler except when the values of both operands are known at compile time. In this case, the sign of the result is the same as the sign of the numerator.

### 5.8 Shift Operators

**Result of right shift**: The *Reference Manual* states that the result of a right shift when the left operand is a signed type with a negative value is implementation dependent. This behavior depends on the underlying C compiler.

### 5.9 Relational Operators

**Pointer comparisons**: According to the *Reference Manual*, certain pointer comparisons are implementation dependent. For Release 2.0, the results of these comparisons depend on the underlying C compiler.

### 7.1.1 Storage Class Specifiers

Inline functions: The *Reference Manual* states that the inline specifier is a hint to the compiler. Release 2.0 performs inline substitution of inline functions wherever possible. Inline calls are not, however, generated in the following cases:

■ For an inline function with a non-void return type, the presence of an iteration, switch, labeled, or goto statement within the inline function precludes generating code inline. In these cases, a warning message is issued and code to call the function out-of-line is generated.

- For an inline function with void return type, the presence of a return statement precludes generating code inline. If a call to such a function is seen, a "not implemented" message is issued.
- For an inline function containing a static object, a "not implemented" message is issued.
- For an inline function containing an automatic array object, a "not implemented" message is issued if the function is called.
- For an inline function containing a recursive call, out-of-line code is generated.
- In general, if a call to an inline function precedes (lexically) the definition of the inline function, an out-of-line call is generated.

These restrictions may be relaxed in future releases of the AT&T C++ Language System.

### 7.1.6 Type Specifiers

Volatile: Release 2.0 does not implement the type specifier volatile; it is ignored and a warning message is issued.

Signed: Release 2.0 does not implement the type specifier signed; it is ignored and a warning message is issued.

#### 7.3 Asm Declarations

Effect of an asm declaration: Release 2.0 passes asm declarations to the underlying C compiler without modification.

## 7.4 Linkage Specifications

Languages supported: Release 2.0 supports linkage to C and C++.

Linkage to functions: The effect of a "C" linkage specification (extern "C") on a function that is not a member function is that the function name is not encoded with type information, as is otherwise done for C++ functions. Member functions are not affected by linkage specifications.

Linkage to non-functions: The "C" linkage specification, (extern "C") when applied to a non-function declaration, does not affect the C code generated.

#### 9.3 Member Functions

Calling a non-static member function: The Reference Manual states that the effect of calling a non-static member function of a class X for something that is not an object of class X is implementation dependent. In such cases Release 2.0 generates code to call the member function and assigns to this the address of the object for which the function is called. This behavior is not guaranteed to be supported in future releases of the AT&T C++ Language System.

#### 9.6 Bit Fields

Allocation and alignment of bit fields: The Reference Manual states that the allocation and alignment of bit fields within a class object is implementation dependent. Responsibility for the allocation and alignment of bit fields rests with the underlying C compiler.

### 13.2 Argument Matching

Integral arguments: The type of the result of an integral promotion (§4.1) depends on the execution environment, as does the type of an unsuffixed integer constant (§2.5.1). Consequently, the determination of which overloaded function to call may also depend on the execution environment, as illustrated by the example in §13.2 of the Reference Manual.

# 14. Templates (experimental)

Release 2.0 does not implement templates. The keyword template is reserved for future use. A "not implemented" message is reported if template is seen.

## 15. Exception Handling (experimental)

Release 2.0 does not implement exception handling. The keyword catch is reserved for future use. A "not implemented" message is reported if catch is seen.

## 16. Compiler Control Lines

Behavior of the preprocessor: Lines beginning with # communicate with the preprocessor. The effect of these lines depends on the underlying preprocessor.

## 16.1 Token Replacement

Predefined macro names: The following macro names are defined by Release 2.0:

The decimal constant 1. cplusplus

The decimal constant 1. This macro name is provided for compatibility with c plusplus

previous releases and is not guaranteed to be supported in future releases.

#### **B.3** Anachronisms

The anachronisms supported in Release 2.0 are not guaranteed to be supported in future releases of the AT&T C++ Language System.

The word overload is reserved. It may be used as a decl-specifier in a function declaration or a function definition; it cannot be used as an identifier.

The definition of a static data member of a class may be omitted. When a definition is not given for a static data member, its initial value will be zero.

The AT&T C++ Language System Release 2.0 does not include a preprocessor. Nothing in Release 2.0 precludes the use of an old-style (that is, pre-ANSI C) C preprocessor.

An int may be assigned to an object of enumeration type.

The number of elements in an array may be left unspecified when deleting an array of a nonclass type.

### **B.3.1 Old Style Function Definitions**

Programs may use the old C function definition syntax.

### **B.3.2 Old Style Base Class Initializer**

The name of the base class may be omitted in a member initializer list when there is exactly one immediate base class.

## **B.3.3** Assignment to this

Release 2.0 allows assignment to this pointers in constructors and destructors to control memory management of class objects.

#### **B.3.4 Cast of Bound Pointer**

Release 2.0 allows casting a pointer to member function for a particular object into a pointer to function. Any use of the resulting pointer is undefined.

# C++ Reference Manual

Appendix D: "Not Implemented" Messages

121

# Appendix D: "Not Implemented" Messages

This appendix contains the text and explanation for all "not implemented" messages produced by the AT&T C++ Language System Release 2.0. They are listed here in alphabetical order.

Each message is preceded by a file name and line number. The line number is usually the line on which a problem has been diagnosed.

"Not implemented" messages cause the CC command to fail; that is, code is not generated, nor is the program linked. Release 2.0 will, however, attempt to examine the rest of your program for other errors.

- & of op
- lvalue op too complicated

An operand required to be an Ivalue or the operand of the unary & operator is an expression that has side effects. The Ivalue or operand of & might be, for example, an assignment expression, an increment operation, or a decrement operation.

```
int i, j;
int *pl = &(++(i%=j));
```

```
"file", line 2: not implemented: ++ of %=
"file", line 2: not implemented: & of ++
```

■ ++ of op

The operand of the ++ operator contains a ?: operator, a comma operator, or an operator that produces side effects, such as = or ++.

```
int i, j;
int k = ++(i+=j);
```

```
"file", line 2: not implemented: ++ of +=
```

■ 1st operand of .\* too complicated

The first operand of a function call expression involves a pointer to a member function and is an expression that may have side effects or may require a temporary.

```
struct S { virtual int f(); };
int (S::*pmf)() = &S::f;
S *f();
int i = (f()->*pmf)();
```

```
"file", line 5: not implemented: 1st operand of .* too complicated
```

■ 2nd operand of .\* too complicated

The second operand of a pointer to member operator is an expression that has side effects.

```
struct S { int f(); };
int (S::*pmf)() = &S::f;
S *sp = new S;
int i = 5;
int j = (sp->*(i+=5, pmf))();
```

```
"file", line 5: not implemented: 2nd operand of .* too complicated
```

■ anonymous unions nested deeper than 2 levels

Anonymous unions are nested to more than two levels.

```
static union {
    union {
        int i;
        union {
            char c;
            int j;
        };
};
```

"file", line 7: not implemented: anonymous unions nested deeper than 2 levels

■ cannot expand inline function function with for statement

A for statement appears in the declaration of an inline function.

```
struct S {
    int s[100];
    S() { for (int i = 0; i < 100; i++) s[i] = i; }
};</pre>
```

```
"file", line 1: not implemented: cannot expand inline function S::S() with for statement
```

■ cannot expand inline function function with return statement

A return statement without an expression appears in the declaration of an inline function.

```
inline void f() {
    return;
}
```

"file", line 2: not implemented: cannot expand inline function f() with return statement

April 1900 And April 1900 April 1

■ cannot expand inline function function with statement after "return"

A value-returning inline function contains a statement following a return statement.

```
inline int f(int i) {
    if (i) return i;
    return 0;
}
```

```
"file", line 4: not implemented: cannot expand inline function f() with statement after "return"
```

■ cannot expand inline function function with two local variables with the same name (name)

Two variables with the same name and different types are declared within the body of a value-returning inline function.

```
inline int f(int i) {
      { int x = i; }
      { double x = i; }
      return 0;
}
```

"file", line 5: not implemented: cannot expand inline function f() with two local variables with the same name (x)

■ cannot expand inline function needing temporary variable in non function context

This message should not be produced.

■ cannot expand inline function needing temporary variable of vector type

An inline function that contains a local declaration of an array object is called.

```
inline int f(int i) {
    int a[1];
    a[0] = i;
    return i;
}
int v = f(0);
```

"file", line 6: not implemented: cannot expand inline function needing temporary variable of vector type

■ cannot expand inline function with return in if statement

This condition occurs as a result of implementation-generated statements. It can be circumvented by avoiding unnecessary return statements in inline functions.

```
struct S {
      S() {return;}
};
```

"file", line 1: not implemented: cannot expand inline function S::S() with statement after "return"

"file", line 1: not implemented: cannot expand inline function with return in if statement

■ cannot expand inline function with static name

An inline function contains the declaration of a static object.

```
inline void f() {
    static int i = 5;
};
```

"file", line 2: not implemented: cannot expand inline function with static i

- cannot expand inline void function called in comma expression
- cannot expand inline void function called in for expression

A call of an inline void function that cannot be translated to an expression (that is, one that includes a loop, a goto, or a switch statement) appears as the first operand of a comma operator or appears in the second expression of a for statement.

```
int i;
void inline fl() { for (;;) ; }
void inline f2() { i += 5; }
void g() { for ( fl(), i=i;;) ; }
void h() { for ( f2(), i=i;;) ; }
void j() { for (;; f1()); }
void k() { for (;; f2()); }
```

"file", line 4: not implemented: cannot expand inline void fl() called in comma expression "file", line 6: not implemented: cannot expand inline void fl() called in for expression

■ cannot expand value-returning inline function with call of ...

A value-returning inline function is defined, and it contains a call to another inline function that is not value-returning.

```
inline void f() { for(;;); }
inline int g() { f(); return 0; }
```

"file", line 2: not implemented: cannot expand value-returning inline g() with call of non-value-returning inline f()

■ cannot merge lists of conversion functions

A derived class with multiple bases is declared and there are conversion operators declared in more than one of the base classes.

```
struct B1 {
          operator int();
};
struct B2 {
          operator float();
};
struct D : public B1, public B2 { };
```

"file", line 7: not implemented: cannot merge lists of conversion functions

■ catch

The keyword catch appears; catch is reserved for future use.

int catch;

```
"file", line 1: not implemented: catch
"file", line 1: warning: name expected in declaration list
```

■ class defined within sizeof

A class definition appears as the type name in a sizeof expression.

```
int i = sizeof (struct S { int i; });
```

"file", line 1: not implemented: class defined within sizeof

■ class hierarchy too complicated

This message should not be produced.

■ conditional expression with type

The second and third operands of a conditional expression are member functions or pointers to member functions.

```
struct S {
    int t;
    f() { return t; }
    g() { return 1; }
    h() { return (t?f:g)(); }
};
```

```
"file", line 5: not implemented: conditional expression with int S::()
"file", line 5: error: object or pointer missing for ? of type int S::()
```

- constructor as default argument
- constructor needed for argument initializer

The default value for an argument is a constructor or is an expression that invokes a constructor.

```
struct S { S(int); };
int f(S = S(1));
int g(S = 5);
```

```
"file", line 2: not implemented: constructor as default argument
"file", line 3: not implemented: constructor needed for argument initializer
```

■ copy of member[], no memberwise copy for class

An implementation-generated copy operation for a class X is required, but the operation cannot be generated because X has an array member of one of the following kinds of types: a class with a virtual base class, a class with a programmer-defined X(XE), or a class with a programmer-defined operator=().

```
struct S1 {};
struct S2 : virtual S1 {};
struct X { S2 m[1]; };
X var1;
X var2 = var1;
```

```
"file", line 5: not implemented: copy of S2[], no memberwise copy for S2
```

■ default argument too complicated

A default argument in a declaration not at file scope requires the generation of a temporary.

```
struct S { int f(int &r = (int) 'x'); };
```

```
"file", line 1: not implemented: default argument too complicated
"file", line 1: not implemented: needs temporary variable to evaluate argument initializer
```

■ default arguments for constructor for array of class name

A constructor with default arguments is invoked to initialize an array of class objects without an explicit initializer.

```
struct S { S(int=5); };
S s[2];
S *sp = new S[2];
```

```
"file", line 2: not implemented: default arguments for constructor for array of class S "file", line 3: not implemented: default arguments for constructor for array of class S
```

■ delete array through pointer or array of arrays

The object deleted by a delete operator has the type "pointer to array of class." This can be either a single- or multi-dimensional array. This error does not occur if the type is "pointer to class."

```
struct S {};
typedef S A1[1];
void f() {
     A1 *p = (A1 *) new A1;
     delete p;
}
```

"file", line 6: not implemented: delete array through pointer or array of arrays

expression in for statement needs temporary of class with destructor An expression in a for statement requires a temporary of a class type for which there is a destructor.

```
struct S { S(int); ~S(); } s(0);
main() {
    for( int i = 10 ; i ; s = --i );
}
```

"file", line 3: not implemented: expression in for statement needs temporary of class S with destructor

■ general initializer in initializer list

The initializer list in a declaration contains an expression that is not constant.

```
int f();
int i[1] = { f() };
```

"file", line 2: not implemented: general initializer in initializer list

■ initialization of automatic aggregate

An aggregate at local scope is initialized. This message is not issued if the +a1 option (produces declarations acceptable to an ANSI C compiler) is specified.

```
void f() {
    int i[1] = {1};
}
```

"file", line 2: not implemented: initialization of automatic aggregate

■ initialization of union with initializer list

An object of union type is initialized with an initializer list. This message is not issued if the +a1 option (produces declarations acceptable to an ANSI C compiler) is specified.

```
union U { int i; float f; };
U u = { 1 };
```

"file", line 2: not implemented: initialization of union with initializer list

- initializer for local static too complicated
  This message should not be produced.
- initializer for multi-dimensional array of objects of class class with constructor name

A multi-dimensional array of a class with a constructor has an explicit initializer.

```
struct S { S(int); };
S s[2][2] = {1,2,3,4};
```

"file", line 2: not implemented: initializer for multi-dimensional array of objects of class S with constructor ::s

■ label in block with destructors

A labeled statement appears in a block in which an object with a destructor exists.

```
struct S { S(int); ~S(); };
void f() {
       S s(5);
xyz: ;
}
```

"file". line 5: not implemented: label in block with destructors

■ local static vector of class class with constructor

A static array of class objects with one or more constructors appears at local scope.

```
class X {
public:
     X();
};
void f()
{
    static X x[9];
}
```

"file", line 2: not implemented: local static vector of class X with constructor

■ local static name has class::-class() but no constructor (add class:: class())

A static class object with a destructor, but no constructor, appears at local scope.

```
struct X { ~X(); };
void f() { static X x; }
```

```
"file", line 1: warning: X has X::-X() but no constructor
"file", line 2: not implemented: local static x has X::-X() but no
constructor(add X:: X())
```

■ lvalue op too complicated See "& of op." ■ needs temporary variable to evaluate argument initializer

A default argument requires a temporary variable.

```
void g() {
    int h(int & = 5);
}
```

"file", line 2: not implemented: needs temporary variable to evaluate argument initializer

■ non-trivial declaration in switch statement

A "non-trivial" declaration appears within a switch statement. Such a declaration might declare an object of reference type, a static object, a const object, an object of a class type with constructor or destructor, an object with an initializer list, or an object initialized with a string literal.

"file", line 2: not implemented: non-trivial declaration in switch statement (try enclosing it in a block)

Note that since it is illegal to jump past a declaration with an explicit or implicit initializer unless the declaration is in an inner block that is not entered, most declarations in switch statements and not contained in inner blocks will be errors.

- pointer expression too complicated for delete
- pointer expression too complicated for delete[]

The delete operator is applied to an object or an array of objects of a type with a virtual destructor, and the operand is not a simple expression.

```
struct S {
         S();
         virtual ~S();
};
S *f();
void g() {
         delete f();
         delete [2] f();
}
```

```
"file", line 9: not implemented: pointer expression too complicated for delete
"file", line 9: not implemented: pointer expression too complicated for delete[]
```

A variable can be introduced to circumvent the unimplemented functionality. For example,

```
void g2() {
    S* sp;
    sp = f();
    delete sp;
}
```

- pointer to member function type too complicated
  - This message should not be produced.

■ pointer to member of not first base

A pointer to member function is initialized with or assigned the address of a member of a base class other than its lexically first base.

```
struct B1 {};
struct B2 { int f(); };
struct D : B1, B2 {};
int (D::*pmf)() = D::f;
```

```
"file", line 4: not implemented: int B2::() assigned to int (D::*)() (too complicated)
"file", line 4: not implemented: pointer to member of not first base
```

■ public specification of overloaded function

The base class member in an access declaration refers to an overloaded function. A similar message is issued for illegal private and protected access declarations.

```
struct B { int f(); int f(int); };
class D : private B {
public:
     B::f;
};
```

```
"file", line 2: not implemented: public specification of overloaded B::f()
```

struct name member name

This message should not be produced.

■ template

The keyword template appears; template is reserved for future use.

```
int template;
```

```
"file", line 1: not implemented: template
"file", line 1: warning: name expected in declaration list
```

■ temporary of class name with destructor needed in expr expression

An expression containing a ?:, ||, or && operator requires a temporary object of a class that has a destructor.

```
struct S { S(int); ~S(); };
S f(int i) {
    return i ? S(1) : S(2) ;
}
```

"file", line 3: not implemented: temporary of class S with destructor needed in ?: expression

■ too few initializers for name

The initializer list for an array of class objects has fewer initializers than the number of elements in the array.

```
struct S { S(int); };
S a[2] = {1};
```

```
"file", line 2: not implemented: too few initializers for ::a
```

■ typel assigned to typel (too complicated)

A pointer is initialized or assigned with an expression whose type is too complicated.

```
struct S1 {};
struct S2 { int i; };
struct S3 : S1, S2 {};
int S3::*pmi = &S2::i;
```

C++ Reference Manual 133

```
"file", line 4: not implemented: int S2::* assigned to int S3::* (too complicated)
```

■ visibility declaration for conversion operator

An access declaration is specified for a conversion operator.

```
struct B { operator int(); };
class D : private B {
public:
    B::operator int;
};
```

"file", line 1: not implemented: visibility declaration for conversion operator

- wide character constant
- wide character string

A wide character constant or a wide character string is used.

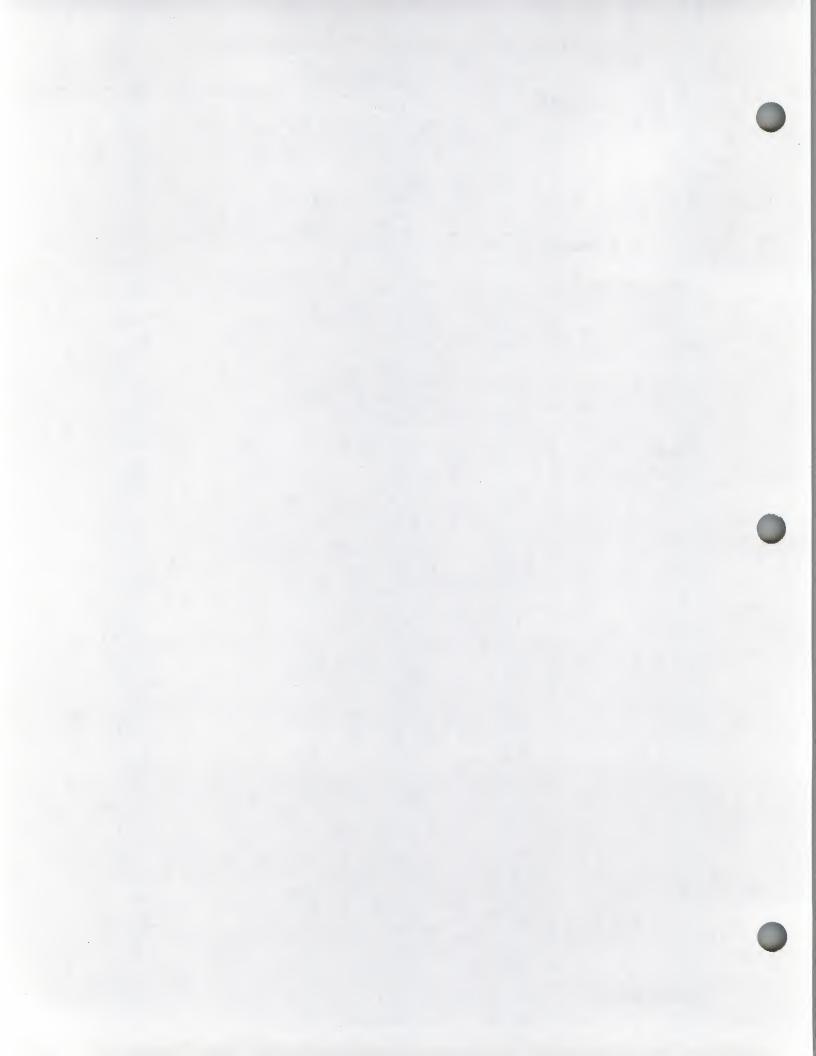

```
int wc = L'ab';
char *ws = L"abcd";
```

```
"file", line 1: not implemented: wide character constant
"file", line 2: not implemented: wide character string
```
